Mechanistic Photochemistry of Inorganic and Organometallic Complexes in Solution and Inert Matrices at 85K

A Dissertation Presented in Partial Fulfillment of the Requirements for the Degree of Doctorate of Philosophy with a

Major in Chemistry
in the

College of Graduate Studies
University of Idaho
by
Wyatt Aaron Thornley

Major Professor: Thomas E. Bitterwolf, Ph.D.
Committee Members: Eric B. Brauns, Ph.D.; John C. Linehan, Ph.D.;
Peter B. Allen, Ph.D.
Department Chair: Ray von Wandruszka, Ph.D.

## Authorization to Submit Dissertation

This dissertation of Wyatt Aaron Thornley, submitted for the degree of Doctorate in Philosophy with a Major in Chemistry and titled "Mechanistic Photochemistry of Inorganic and Organometallic Complexes in Solution and Inert Matrices at 85K," has been reviewed in final form. Permission, as indicated by the signatures and dates below, is now granted to submit final copies to the College of Graduate Studies for approval.

#### Abstract

Matrix-isolation FTIR at cryogenic temperatures and traditional solution experiments have been used to study the mechanisms of new and previously reported photochemical reactions of inorganic and organometallic complexes. Spurred by lack of consensus for the mechanism of the photodecomposition of permanganate, one of the earliest reported inorganic photoreactions, a broad survey upon the photochemistry of inorganic and organometallic oxides and nitrides was conducted. These studies yielded the only known example of reversible six-electron reductive elimination and oxidative addition, coming in the form of a nitrosyl ligand from the nitridoosmate anion, the identity of the key intermediate and mechanism of the photodecomposition of permanganate, and a new competitive photopathway in the photochemistry of the $\mathrm{O}_{2}$ adduct of Vaska's complex, an archetypal organometallic photoreaction.

As a means to study the structure and bonding of the [FeFe]-hydrogenase enzyme active, a potential model for a future hydrogen energy economy, the photochemistry of structural models of this active site has been studied. At cryogenic temperatures, photoejection of CO is observed resulting in a product that may then undergo secondary photolysis to form either a bridging carbonyl ligand as found in the natural enzyme, or result in C-H bond activation of the alkyl dithiolate bridge which may serve as a new model for proton or hydride transfer in the catalytic cycle of the [FeFe]-hydrogenase enzyme. Photodecarbonylation of dithiolene
derivatives of [FeFe]-hydrogenase model complexes results in the formation of uncommon aromatic metallacycles.

Photolysis of a series of allyl complexes in the $\mathrm{TpM}(\mathrm{CO})_{2}\left(\eta^{3}-\mathrm{C}_{3} \mathrm{H}_{4} \mathrm{R}\right)$, where Tp=tris(pyrazolyl)borate, $\mathrm{M}=\mathrm{Mo}$ or W , and $\mathrm{R}=2-\mathrm{H}$ or 2-Me, family of compounds was found to result in in exo/gauche rotameric isomerism of the allyl ligand, exhibiting behaviour distinct from the closely related $\mathrm{CpM}(\mathrm{CO})_{2}\left(\eta^{3}-\mathrm{C}_{3} \mathrm{H}_{4} R\right) \quad\left(\mathrm{Cp}=\eta^{5}-\right.$ cyclopentadienyl) complexes that undergo endo/exo rotameric isomerism.

Finally, a series of organometallic diazonium complexes were studied at cryogenic temperatures. Diazonium ligands are isoelectronic with the well-studied nitrosyl ligand, and these initial studies reveal, that like their nitrosyl counterparts, diazonium ligands undergo $\eta^{1}$ to $\eta^{2}$ linkage isomerism following photoexcitation. An additional photoreaction, whereby homolysis of the diazonium ligand occurs to yield two radical species is also reported.

# Chapter 1: Photochemical Intramolecular Six-Electron Reductive Elimination and Oxidative Addition of Nitric Oxide by the Nitridoosmate(VIII) Anion 

Published: W. A. Thornley, T. E. Bitterwolf, Angew. Chem. Int. Ed. Engl. 2015, 54, 2068-2072.

#### Abstract

UV photolysis of the nitridoosmate(VIII) anion, $\mathrm{OsO}_{3} \mathrm{~N}$, in low-temperature frozen matrices results in nitrogen-oxygen bond formation to give the Os(II) nitrosyl complex $\mathrm{OsO}_{2}(\mathrm{NO})^{-}$. Photolysis of the $\mathrm{Os}(\mathrm{II})$ nitrosyl product with visible wavelengths results in reversion to the parent Os(VIII) complex. Formally a 6-electron reductive elimination and oxidative addition, respectively, this represents the first reported example of such an intramolecular transformation. DFT modelling of this reaction reveals a step-wise mechanism taking place through a side-on nitroxyl Os(VI) intermediate, $\mathrm{OsO}_{2}\left(\eta^{2}-\mathrm{NO}\right)$.

Oxidative addition and reductive elimination reactions are fundamental processes observed in transition metal chemistry. These are generally two-electron processes that are associated with addition or elimination of substrates such as $\mathrm{H}_{2}$, alkanes, arenes, silanes, and others, and have been widely exploited in a variety of catalytic cycles. Far less common are the four- or six-electron analogues of these reactions.

Four- and six-electron oxidative addition of bonds in $\mathrm{N}_{2} \mathrm{O}$ have been observed in a number of chemical systems. ${ }^{1}$ In frozen gas matrices, metal atoms ${ }^{2-4}$ and vacant metal sites generated through photochemical decarbonylation, ${ }^{5,6}$ reactions have been observed with $\mathrm{O}_{2}, \mathrm{NO}$, and $\mathrm{N}_{2}$ to form $\mathrm{OMO}, \mathrm{NMO}$, and NMN species, respectively; in some cases these products may be preceded by an $\eta^{2}-X Y$ species with conversion to the insertion product being either thermally or photochemically initiated. In an examination of the photochemistry of $\mathrm{CpW}(\mathrm{CO})_{2} \mathrm{NO}\left(\mathrm{Cp}=\eta^{5}-\mathrm{C}_{5} \mathrm{H}_{5}\right)$ in frozen gas matrices, Rest and co-workers found evidence for intramolecular formation of an isocyanate ligand to give $\mathrm{CpW}(\mathrm{CO})(\mathrm{NCO})$, presumably through the reaction of CO with a photochemically generated nitrene intermediate; the ultimate fate of O-atom of the nitrosyl ligand remains elusive. ${ }^{7}$ In a solution photolysis study of the closely related $\mathrm{CpMo}(\mathrm{CO})_{2} \mathrm{NO}$ in the presence of an excess of $\mathrm{PPh}_{3}, \mathrm{McPhail}$ and co-workers found that in addition to the simple $\mathrm{PPh}_{3}$ substitution product, generation of $\mathrm{PPh}_{3} \mathrm{O}, \mathrm{CpMo}(\mathrm{CO})_{2}(\mathrm{NCO}) \mathrm{PPh}_{3}$, and $\mathrm{CpMo}(\mathrm{CO})(\mathrm{NCO})\left(\mathrm{PPh}_{3}\right)_{2}$ were also observed, providing evidence for intramolecular activation of the nitrosyl ligand to give an unobserved nitrene intermediate. ${ }^{8}$ Finally, Legzdins and co-workers have observed isomerization of some 16-electron aryl and alkyl nitrosyl complexes of tungsten to the corresponding imido oxo analogues when in the presence of $\mathrm{O}_{2}$ or $\mathrm{H}_{2} \mathrm{O}$; in the latter case an $\eta^{2}-\mathrm{NO}$ intermediate was suggested. ${ }^{9-21}$

Even less common are the four- and six-electron reductive elimination counterparts to these multi-electron oxidative additions. We are only aware of two such examples that fit this category; the long-known photochemical ejection of $\mathrm{O}_{2}$
from the permanganate ion ${ }^{22}$ and $S_{2}$ from $\mathrm{MS}_{4}{ }^{\mathrm{n}}$, where $\mathrm{M}, \mathrm{n}=\mathrm{Mo}, 2 ; \mathrm{W}, 2$; $\mathrm{V}, 3$; and Re, 1 when in the presence of $\mathrm{O}_{2} .{ }^{23,24}$

As part of our ongoing examination of metal nitrosyl photochemistry, our attention was directed toward the possibility that the photochemical nitrosyl bond cleavage reported by Rest and McPhail may occur through oxidative addition of a photogenerated $\eta^{2}-\mathrm{NO}$ intermediate. Oxidative addition of an $\eta^{2}$-NO may give rise to several valence isomers depending upon the extent of reduction of the nitrosyl ligand, each possessing the same ligating atoms but differing in the nature of the bonds between the ligands and metal as well as the oxidation state of the metal. Formal four-electron oxidative addition of the nitrosyl ligand in $\mathrm{CpM}(\mathrm{CO})_{2}\left(\eta^{2}-\mathrm{NO}\right)$ would result in formation of what could be described as an anionic $\eta^{2}-\mathrm{NO}$ nitroxyl group and six-electron oxidative addition would result in cleavage of the NO bond to ultimately yield a mixed nitride oxide complex (Scheme 1.1).

C

Scheme 1.1: Valence isomers of $\mathrm{CpM}(\mathrm{CO})_{2}\left(\eta^{2}-\mathrm{NO}\right)$

Synthesis of four-electron valence isomers of a molybdenum nitrosocomplex has been previously reported. Wentworth and Maatta synthesized the $\eta^{2}$ nitrosobenzene complex $\mathrm{Mo}\left(\eta^{2}-\mathrm{ONPh}\right)\left(\mathrm{S}_{2} \mathrm{CNEt}_{2}\right)_{2}$, as well as its four-electron valence
isomer $\mathrm{MoO}(\mathrm{NPh})\left(\mathrm{S}_{2} \mathrm{CNEt}_{2}\right)_{2}$, a mixed phenylnitrene, oxo complex. ${ }^{24}$ Though no isomerization between $\mathrm{Mo}\left(\eta^{2}-\mathrm{ONPh}\right)\left(\mathrm{S}_{2} \mathrm{CNEt}_{2}\right)_{2}$ and $\mathrm{MoO}(\mathrm{NPh})\left(\mathrm{S}_{2} \mathrm{CNEt}_{2}\right)_{2}$ was found to occur thermally nor following visible photolysis, in a subsequent publication we will demonstrate that this process does, indeed, occur at higher energies of incident light. ${ }^{25,26}$ This remarkable example does demonstrate the ability of a transition metal to support such valence isomers as those proposed for the oxidative-addition of an $\eta^{2}$-NO ligand.

As no direct evidence for $\eta^{2}$-NO valence isomerism has been reported in metal nitrosyl photochemistry literature, we directed our focus on the photochemistry of model compounds that resemble the oxidative addition valence isomers of $\eta^{2}-\mathrm{NO}$, that is, complexes with oxide and nitride ligands oriented in adjacent coordination sites. Microscopic reversibility indicates that if an $\eta^{2}$-NO ligand is capable of undergoing oxidative addition, that this family of compounds should then be able to reductively eliminate nitric oxide (Scheme 1.2). Matching this criteria is the $\mathrm{MO}_{3} \mathrm{~N}^{\mathrm{n}}$ family of compounds where $\mathrm{M}, \mathrm{n}=\mathrm{Mo}, 3$; Re, 2; and $\mathrm{Os}, 1 .{ }^{8}$ Due to poor solubility of the polyanions, only $\left.\left[\left(n-\mathrm{C}_{4} \mathrm{H}_{9}\right)_{4} \mathrm{~N}\right)\right]\left[\mathrm{OsO}_{3} \mathrm{~N}\right]$ was found to be compatible with the matrix materials we currently use for low-temperature photolysis experiments.

Scheme 1.2: Proposed reductive elimination of nitric oxide by $\mathrm{OsO}_{3} \mathrm{~N}$.

Figure 1.1: Electronic spectrum of $\left.\left[\left(n-\mathrm{C}_{4} \mathrm{H}_{9}\right)_{4} \mathrm{~N}\right)\right]\left[\mathrm{OsO}_{3} \mathrm{~N}\right]$ as a thin film at 85 K .

The electronic spectrum of $\left.\left[\left(n-\mathrm{C}_{4} \mathrm{H}_{9}\right)_{4} \mathrm{~N}\right)\right]\left[\mathrm{OsO}_{3} \mathrm{~N}\right]$ as a thin film at 85 K in the region of $250-500 \mathrm{~nm}\left(20,000-40,000 \mathrm{~cm}^{-1}\right)$ consists of three overlapping absorptions centered at 402, 357, and 315 nm with well resolved vibronic fine structure (Figure 1.1). Miskowski and coworkers have previously performed a detailed analysis of the vibronic fine structure of the electronic spectrum of nitridoosmate(VIII) at 5 K , and found an average $\Delta v$ of $825 \mathrm{~cm}^{-1}, 900 \mathrm{~cm}^{-1}$, and 872 $\mathrm{cm}^{-1}$ for the three absorptions bands, respectively. ${ }^{30}$ This coupling corresponds to an 11-19\% reduction of the Os-N stretching frequency in the excited state, consistent with LMCT from the nitride ligand. TD-DFT calculations reveal that these three absorptions consist of vertical excitations from non-bonding nitride and oxide
p-orbitals to molecular orbitals that are predominantly metal d-orbital in character. It is worth noting that the non-bonding nitrogen and oxygen p-orbitals of the LUMO are oriented in such a way that occupation of this orbital, accompanied by a molecular vibration along the $\mathrm{C}_{\mathrm{s}}$ symmetry plane, may lead to a bonding $\mathrm{N}-\mathrm{O}$ interaction.

Figure 2.2: Selected Kohn-Sham orbitals of $\mathrm{OsO}_{3} \mathrm{~N}^{-}$from non-relativistic

In a triethyloctylammonium tetrafluoroborate matrix at 85 K , [(n$\left.\left.\left.\mathrm{C}_{4} \mathrm{H}_{9}\right)_{4} \mathrm{~N}\right)\right]\left[\mathrm{OsO}_{3} \mathrm{~N}\right]$ exhibits three well resolved vibrational modes, an antisymmetric Os-O stretching mode at $872 \mathrm{~cm}^{-1}$, a fully symmetric Os-O stretching mode at 889 $\mathrm{cm}^{-1}$, and the Os-N stretch at $1014 \mathrm{~cm}^{-1}\left(982 \mathrm{~cm}^{-1}\right.$ for the ${ }^{15} \mathrm{~N}$ isotopomer) (Figure 1.3). Photolysis of the sample with $330 \pm 50 \mathrm{~nm}$ irradiation results in bleaching of the parent vibrational bands and growth of two new strong Os-O vibrational modes at $880 \mathrm{~cm}^{-1}$ and $918 \mathrm{~cm}^{-1}$, and an intense absorption at $1,620 \mathrm{~cm}^{-1}$ that shifts to 1584 $\mathrm{cm}^{-1}$ upon ${ }^{15} \mathrm{~N}$ substitution (Figure 1.3a). Back photolysis of the $330 \pm 50 \mathrm{~nm}$ irradiated sample with $400 \pm 35 \mathrm{~nm}$ light results in reversion of the initial photoproduct to the parent compound (Figure 1.3b).

The most notable feature of the $330 \pm 50 \mathrm{~nm}$ irradiation photoproducts is the ${ }^{15} \mathrm{~N}$ sensitive absorption at $1620 \mathrm{~cm}^{-1}$. This new band lies within the metal-nitrosyl stretching region and well beyond the typical metal-oxo or metal-nitrido stretching region, demonstrating the generation of new $\mathrm{N}-\mathrm{O}$ bonds in the molecule following UV photolysis. The weaker absorption at $918 \mathrm{~cm}^{-1}$ shifts to $914 \mathrm{~cm}^{-1}$ upon ${ }^{15} \mathrm{~N}$ substitution, indicating that the molecular vibration is weakly coupled to the N atom. The ratio of the intensity of these two bands is highly dependent upon the duration of photolysis, sample concentration, and the thickness of the matrix, suggesting that these vibrations belong to two different photoproducts. Back photolysis of these two products with $400 \pm 35 \mathrm{~nm}$ light results in reversion to the parent complex at differing rates, demonstrating that the two photoproducts have overlapping electronic absorptions in this region.

Figure 1.3: Photolysis of $\left.\left[\left(n-\mathrm{C}_{4} \mathrm{H}_{9}\right)_{4} \mathrm{~N}\right)\right]\left[\mathrm{OsO}_{3} \mathrm{~N}\right]$ in $\left[\mathrm{Oct}_{3} \mathrm{EtN}\right]\left[\mathrm{BF}_{4}\right]$ matrix at 85 K . Top
(a) Difference following $330 \pm 50 \mathrm{~nm}$ irradiation from unphotolyzed sample. Bottom
(b) Difference following $400 \pm 35 \mathrm{~nm}$ backphotolysis of $330 \pm 50 \mathrm{~nm}$ irradiated sample. Results of photolysis of $\left.\left[\left(n-\mathrm{C}_{4} \mathrm{H}_{9}\right)_{4} \mathrm{~N}\right)\right]\left[\mathrm{OsO}_{3}{ }^{15} \mathrm{~N}\right]$ presented as red trace.

While the new absorption at $1620 \mathrm{~cm}^{-1}$ is strongly indicative of the presence of a linear metal-nitrosyl photoproduct, the identity of the secondary photoproduct primarily characterized by an absorption at $918 \mathrm{~cm}^{-1}$ is less clear. One possibility is the formation of a bond between two oxide ligands which would give rise to a peroxo O-O vibrational mode that would absorb in this region, however, the lack of any new absorptions assignable to the Os-N stretching mode of such a molecule makes this assignment unlikely. A more probable candidate is a species intermediate to the parent complex and the putative nitrosyl complex, that is, a species with a partially reduced metal center and a weak $\mathrm{N}-\mathrm{O}$ bond such as that of structure 1c (Scheme 1.3). To clarify the nature of the photoproducts observed in our matrix photolysis experiments, a DFT investigation was performed to identify any possible species possessing $\mathrm{N}-\mathrm{O}$ and $\mathrm{O}-\mathrm{O}$ bonds.

Scheme 1.3: Lowest energy DFT stationary point geometries considered.

DFT studies revealed a single stationary point with a NO group in an $\eta^{2}$ coordination mode, a species possessing $C_{s}$ symmetry analogous to 1.1 c calculated to lie $39.5 \mathrm{kcal} \mathrm{mol}^{-1}$ higher in energy than the parent complex. The elongated $\mathrm{N}-\mathrm{O}$
bond length of $1.424 \AA$ calculated for this species is consistent with a $\mathrm{N}-\mathrm{O}$ single bond. Previous DFT and photocrystallography experiments have demonstrated that nitrosyl N-O bond lengths remain nearly constant upon undergoing linkage isomerism, ${ }^{31}$ suggesting that this elongation is not due to the mode of NO coordination, but rather the NO remaining highly anionic and better being described as an $\eta^{2}$-nitroxyl group. This would correspond to the metal having undergone a formal two-electron reduction. Calculated vibrational modes for this species, Table 1.1, show the expected intensity of the $\mathrm{N}-\mathrm{O}$ bond stretch to be much less than that of the Os-O stretching modes, offering an explanation as to why no ${ }^{15} \mathrm{~N}$ sensitive N O absorption is observed for this photoproduct. Compellingly, the fully symmetric Os-O stretching mode is weakly coupled to the $\mathrm{N}-\mathrm{O}$ bond stretching mode and upon ${ }^{15} \mathrm{~N}$ substitution is calculated to decrease in energy from $923 \mathrm{~cm}^{-1}$ to $919 \mathrm{~cm}^{-1}$, consistent with the experimentally observed shift from $918 \mathrm{~cm}^{-1}$ to $914 \mathrm{~cm}^{-1}$.

Only one stationary geometry was found that featured NO in an $\eta^{1}$ coordination mode, a $\mathrm{C}_{2 \mathrm{v}}$ symmetric complex with a linear nitrosyl group calculated to lie $27.6 \mathrm{kcal} \mathrm{mol}^{-1}$ higher in energy than the parent complex, 1.1e. This geometry gave calculated $\mathrm{N}-\mathrm{O}$ and $\mathrm{Os}-\mathrm{O}$ vibrational modes in excellent agreement with those observed in the matrix photolysis experiments. Formally, the Os metal center would be in the +2 oxidation state for this molecule, representing a net six-electron reduction from the parent complex. Additionally, a stationary geometry possessing a peroxo ligand, 1.1 g , was found to lie $61.2 \mathrm{kcal} \mathrm{mol}^{-1}$ higher in energy than the parent complex.

Table 1.1: Calculated QZ4P SO-TPSS-D3(BJ) vibrational frequencies $\left(\mathrm{cm}^{-1}\right)$ and intensities $\left(\mathrm{km} \mathrm{mol}^{-1}\right)$ in parentheses for selected species. Values in red are those calculated for ${ }^{15} \mathrm{~N}$ substitution.

| Compound | Os-N | $\mathrm{N}-\mathrm{O}$ | Os-O |

To better understand the relationship between these stationary points, transition state geometries on the potential energy surface were located; the results of these calculations are presented in Scheme 1.4. In all cases, calculated vibrational modes of the transition states yielded a single large magnitude imaginary frequency and following the intrinsic reaction coordinate of these transition states yielded the expected stationary geometries. The barriers for the conversion of 1.1 a to 1.1 c and 1.1c to 1.1 e are of very similar value at $60.4 \mathrm{kcal} \mathrm{mol}^{-1}$ and $61.5 \mathrm{kcal} \mathrm{mol}^{-1}$, respectively. The barrier for the formation of 1.1 g was calculated at $86.4 \mathrm{kcal} \mathrm{mol}^{-1}$, significantly higher in energy than that required for the formation of the nitrosyl species.

Scheme 1.4: SO-TPSS-D3(BJ) calculated reaction energy diagram for the observed photochemical transformation. Values in parentheses are from SRB88P86 calculations.

On basis of the results of DFT calculations, we dismiss the possibility of UVphotolysis driven O-O bond formation to give an identifiable peroxo species in our low-temperature matrix photolysis experiments. The calculated barrier and stationary point energies for the peroxo complex are roughly $20 \mathrm{kcal} \mathrm{mol}{ }^{-1}$ higher in energy than the corresponding $\mathrm{N}-\mathrm{O}$ bond formation processes. Additionally, the absence of a new experimentally observable Os- N stretch in the photolysis products as well as the absence of any calculated ${ }^{15} \mathrm{~N}$ coupled Os-O vibrational modes in the peroxo complex makes 1.1 g inconsistent as one of the observed photoproducts.

We then identify the non-nitrosyl photoproduct generated during matrix photolysis as structure 1.1c. DFT calculations found this partially reduced $\mathrm{Os}(\mathrm{VI})$ species to connect the $\mathrm{Os}(\mathrm{VIII})$ parent complex, 1.1a, to the $\mathrm{Os}(\mathrm{II})$ nitrosyl complex, 1.1e, on the potential energy surface, making it a probable intermediate in the formation of the Os(II) nitrosyl complex. Furthermore, the small magnitude shift of the symmetric OsO vibrational mode upon ${ }^{15} \mathrm{~N}$ substitution for complex 1.1 c is accurately reproduced by DFT. The identity of the species giving rise to the absorptions at $1620 \mathrm{~cm}^{-1}$ and $880 \mathrm{~cm}^{-1}$ is then assigned to complex 1.1 e which is fully consistent with experimental spectroscopic data and DFT calculations.

The exact mechanism of this transformation remains unclear. As the matrix photolysis experiments are conducted under steady-state photolytic conditions, multi-step and multi-photon reactions are possible. In the present case, this would correspond to the absorption of a photon by the parent complex, 1.1a, to form complex 1.1c, which may then undergo secondary photolysis to form the nitrosyl complex 1.1e. This would necessitate electronic overlap of 1.1 a and 1.1 c in the 330 $\pm 50 \mathrm{~nm}$ region to proceed in this manner. Furthermore, back photolysis of 1.1 c and 1.1e with $400 \pm 35 \mathrm{~nm}$ light results in reversion of both species to the parent complex, 2.1a. Under these conditions, 1.1c reverts to the parent complex faster than 1.1 e by comparison of the ratio of the two initially formed upon UV photolysis of the parent complex. This demonstrates electronic overlap of 1.1 c and 1.1 e assignable as MLCT in this region with reversion of 1.1 c being the favored process. These data support a stepwise, two-photon process as opposed to a single-photon reaction that would be more likely to give only a single observable photoproduct.

In conclusion, a reversible photolytic six-electron reductive elimination and oxidative addition of nitric oxide by the nitridoosmate(VIII) anion has been demonstrated. To the best of our knowledge, this represents the first example of such a reaction. The results of this study offer a possible mechanism for the photochemical disproportionation of the nitrosyl ligand observed in previous studies. Moreover, this has broad implications for the development of catalytic small molecule activation that may be beneficial to the functionalization of abundant chemical feedstocks.

## Experimental

$\left.\left[\left(n-\mathrm{C}_{4} \mathrm{H}_{9}\right)_{4} \mathrm{~N}\right)\right]\left[\mathrm{OsO}_{3} \mathrm{~N}\right]$ was prepared according to literature procedures. ${ }^{30}[(n-$ $\left.\left.\left.\mathrm{C}_{4} \mathrm{H}_{9}\right)_{4} \mathrm{~N}\right)\right]\left[\mathrm{OsO}_{3}{ }^{15} \mathrm{~N}\right]$ was prepared from $98 \%{ }^{15} \mathrm{~N}$ ammonium hydroxide supplied from Cambridge Isotope Laboratories. The apparatus and methods for matrix photochemistry have been reported elsewhere. ${ }^{32}$ Briefly, $2-5 \mathrm{mg}$ of $[(n-$ $\left.\left.\left.\mathrm{C}_{4} \mathrm{H}_{9}\right)_{4} \mathrm{~N}\right)\right]\left[\mathrm{OsO}_{3} \mathrm{~N}\right]$ was thoroughly mixed with $\sim 2 \mathrm{~g}\left[\mathrm{Oct}_{3} \mathrm{EtN}\right]\left[\mathrm{BF}_{4}\right]$ in a mortar and pestle. Approximately 50 mg of this waxy mixture was placed onto a 25 mm NaCl optical round and heated until the wax melted and uniformly spread across the window surface. The sample was allowed to slowly cool over the course of 60 minutes to obtain a clear, optically consistent film. The sample was then placed in a liquid $\mathrm{N}_{2}$ cryostat (Graesby Specac GS21525), and placed under vacuum to obtain an ultimate pressure of $10^{-4}$ torr using a Kontes oil diffusion pump backed by an Edwards RV5 rotary vane pump. After achieving final vacuum, the sample was cooled with liquid $\mathrm{N}_{2}$, obtaining an ultimate temperature of 85 K at the sample. A
reference FTIR spectrum was taken (Perkin Elmer Spectrum 1000, $4 \mathrm{~cm}^{-1}$ resolution, 256 scans averaged), and the sample was photolyzed for 15 minutes in $\sim 50 \mathrm{~nm}$ windows from 600-200 nm, collecting FTIR following each photolysis. The filtered output of a 350 W high-pressure Hg lamp was used (Newport Corporation) for all photolyses. This output was first filtered through a 5 cm pathlength quartz water jacket to absorb the infrared output of the lamp and avoid sample heating, then desired photolysis wavelengths were selected using combinations of optical bandpass and cutoff filters (Hoya, Corion, and Schott).

All DFT calculations were performed in the Amsterdam Density Functional (ADF2013.01) program. ${ }^{33-35}$ Electronic configurations of atoms were described by an all-electron quadruple- $\zeta$ Slater-type orbital basis set modified by four polarization functions (QZ4P STO). ${ }^{36}$ Geometry optimizations and vibrational frequency calculations were performed using the GGA functional of Becke ${ }^{37}$ and Perdew ${ }^{38,39}$ as well as the dispersion corrected meta-GGA TPSS-D3(BJ). ${ }^{40-42}$ Computations carried out using the B88P86 functional utilized a scalar relativistic correction, whereas TPSS-D3(BJ) computations used spin-orbit relativistic corrections within the Zeroth Order Regular Approximation (ZORA). ${ }^{43,44}$ Open-shell calculations were performed to identify any possible $S=1$ or $S=2$ geometries, in all cases these were strongly energetically disfavored. The intrinsic reaction coordinate (IRC) of all calculated transition state geometries was followed to confirm the relation with the expected stationary points. Electronic excitation energies were computed using SOC-B88P86 and the statistical average of orbital potentials (SAOP) model. ${ }^{45,46}$

# Chapter 2: Photochemistry of the Permanganate Ion in LowTemperature Frozen Matrices. 

Published: W. A. Thornley, T. E. Bitterwolf, Inorg. Chem. 2015, 54, 3370-3375.

#### Abstract

Photolysis of the permanganate anion, $\mathrm{MnO}_{4}^{-}$, in tetralkylammonium tetrafluoroborate matrices at 85 K results in formation of the $M n(V)$ peroxo complex, $\mathrm{MnO}_{2}\left(\eta^{2}-\mathrm{O}_{2}\right)^{-}$. Previously postulated to be an intermediate in the photodecomposition of permanganate, results from variable temperature and intensity dependence solution photolysis experiments suggest that $\mathrm{MnO}_{2}\left(\eta^{2}-\mathrm{O}_{2}\right)^{-}$does not lose $\mathrm{O}_{2}$ thermally nor photochemically. A mechanism is proposed in which $\mathrm{MnO}_{2}\left(\eta^{2}-\mathrm{O}_{2}\right)^{-}$is formed through vibrational relaxation of an excited $\left[\mathrm{MnO}_{4}^{-}\right]^{*}$ species that may undergo relaxation through an alternative mechanism that results in formation of the $\mathrm{MnO}_{2}{ }^{-}$ and $\mathrm{O}_{2}$ photodecomposition products.

The photodecomposition of permanganate was first described in 1910. ${ }^{1}$ In this account, Pougnet reported that when in the presence of oxalic acid, photolysis of potassium permanganate solutions lead to reduction of permanganate and formation of potassium manganate. Shortly thereafter, Mathews and Dewey described the photodecomposition of potassium permanganate in the presence of sulfuric acid. ${ }^{2}$ The first detailed studies of this photodecomposition were performed by Rideal and Norrish in 1923, who identified $\mathrm{O}_{2}$ as a product of the reaction. ${ }^{3,4}$

Zimmerman later determined through ${ }^{18} \mathrm{O}$ labeling experiments that the $\mathrm{O}_{2}$ evolved over the course of this reaction was generated intramolecularly and not through the reaction of a permanganate photoproduct and $\mathrm{H}_{2} \mathrm{O} .{ }^{5}$ In this same work, it was also reported that there is a slight thermal dependence on the rate of photodecomposition when photolyzed with wavelengths longer than 436 nm and that the intensity of photolysis had no effect on the quantum yield of the reaction. Two overall decomposition routes were suggested, Scheme 2.1. The lack of appearance of $\mathrm{O}_{2}{ }^{-}$in subsequent EPR experiments ruled out reaction 2, leaving $\mathrm{MnO}_{2}{ }^{-}$and $\mathrm{O}_{2}$ as the ultimate products. ${ }^{6,7}$ Formally, this is a four-electron reductive elimination of $\mathrm{O}_{2}$.

& \text { (2) } \mathrm{MnO}_{4}^{-} \xrightarrow{\mathrm{h} v} \mathrm{MnO}_{2}+\mathrm{O}_{2}^{-}
\end{aligned}
$$

Scheme 2.1: Proposed single-step photodecomposition products of permanganate.

Lee and coworkers later studied the photochemistry of permanganate in aqueous solution using oxidizable substrates as chemical traps. ${ }^{8}$ In this elegant work, it was determined that a photochemical intermediate with a lifetime sufficiently long to undergo bimolecular reactions was generated. It was proposed that this intermediate could revert to permanganate, decompose to $\mathrm{MnO}_{2}{ }^{-}$and $\mathrm{O}_{2}$, or react with an oxidizable substrate, Scheme 2.2. The identity of this intermediate was
assigned to an unobserved $\mathrm{Mn}(\mathrm{V})$ peroxo complex, $\mathrm{MnO}_{2}\left(\mathrm{n}^{2}-\mathrm{O}_{2}\right)^{-}$. A pair of computational studies performed by Nakai and coworkers on the formation of the putative peroxo complex demonstrated an energetically accessible pathway from permanganate to a $\mathrm{C}_{2 v}$ symmetric $\mathrm{MnO}_{2}\left(\eta^{2}-\mathrm{O}_{2}\right)^{-}$complex. ${ }^{9,10}$ It was argued that the energy barrier associated with the change of symmetry from the $T_{d}$ symmetric permanganate ion was responsible for the long lifetime of the photo-generated intermediate.

Scheme 2.2: Proposed mechanism for two-step photodecomposition of permanganate.

A subsequent computational study of this photodecomposition reaction by Gutsev and coworkers yielded two favored pathways, both occurring through a peroxo intermediate. ${ }^{11}$ In the first proposed decomposition mechanism, photoexcitation of permanganate results in formation of the same peroxo intermediate suggested by Lee and Nakai. This intermediate then undergoes secondary excitation resulting in photoejection of an electron and formation of a neutral superoxo complex that may spontaneously lose $\mathrm{O}_{2}$ to give $\mathrm{MnO}_{2}$ and $\mathrm{O}_{2}$ as
products, Scheme 2.3. The second suggested mechanism begins with formation of the same peroxo intermediate followed by secondary excitation to a bis-peroxo complex, $\mathrm{Mn}\left(\mathrm{n}^{2}-\mathrm{O}_{2}\right)_{2}^{-}$, which may undergo spontaneous $\mathrm{O}_{2}$ loss to give $\mathrm{MnO}_{2}^{-}$.

Scheme 2.3: Mechanisms of permanganate photodecomposition suggested by Gutsev et al.

Given the iconic stature of the permanganate ion in inorganic chemistry and ubiquitous presence in laboratories, we were surprised to find no reports of direct experimental characterization of the intermediate proposed by Lee and others. Timeresolved flash-photolysis studies of permanganate have reported no observable photoproducts, ${ }^{12,13}$ and reported low-temperature steady-state photolyses in rigidmatrices have been characterized by EPR, allowing only paramagnetic products to be identified. As part of our group's ongoing study of photogenerated metastable species in low-temperature matrices by FTIR, we turned our attention towards the characterization of the intermediate(s) in the photochemical decomposition of permanganate.

## Electronic Spectrum of the Permanganate Ion

The electronic spectrum of the permanganate ion has been the subject of numerous studies. ${ }^{14-19}$ In aqueous solution, permanganate exhibits LMCT bands at 525, 344, 311, and 229 nm . When doped into $\mathrm{Ba}\left(\mathrm{ClO}_{4}\right)_{2}$ crystals at 4 K , the vibronic fine structure present in the 525 and 311 nm bands becomes well resolved and is dominated by $\Delta v$ progressions of 762 and $757 \mathrm{~cm}^{-1}$, respectively, corresponding to an approximately $16 \%$ reduction of the $\mathrm{Mn}-\mathrm{O}$ stretching mode in the excited state. TD-DFT calculations on the electronic excitations of permanganate generally assign the 525 nm absorption as the $\mathrm{HOMO} \rightarrow$ LUMO $\left(1 \mathrm{t}_{1} \rightarrow 2 \mathrm{e}\right)$ transition, the 344 nm absorption as predominantly $\mathrm{HOMO}-1 \rightarrow \mathrm{LUMO}\left(6 \mathrm{t}_{2} \rightarrow 2 \mathrm{e}\right)$, the 311 nm band as primarily $\mathrm{HOMO} \rightarrow \mathrm{LUMO}+1 \quad\left(1 \mathrm{t}_{1} \rightarrow 7 \mathrm{t}_{2}\right)$, and the 229 absorption as HOMO $1 \rightarrow$ LUMO $+1 \quad\left(6 \mathrm{t}_{2} \rightarrow 7 \mathrm{t}_{2}\right)$, however, considerable mixing of these one-electron transitions is calculated to occur. ${ }^{20-23}$ It is worth noting that the non-bonding oxygen p-orbitals of the $2 e$ molecular orbital are oriented in such a way that occupation of this orbital, accompanied by a molecular vibration of e symmetry, may lead to an OO bonding interaction that would result in the formation of a peroxo complex.

## Photolysis of Permanganate in $\left[\mathrm{Et}_{3} \mathrm{OctN}\right]\left[\mathrm{BF}_{4}\right]$ at 85 K

Photolysis of $\left[\mathrm{Et}_{3} \mathrm{OctN}\right]\left[\mathrm{MnO}_{4}\right]$ in a $\left[\mathrm{Et}_{3} \mathrm{OctN}\right]\left[\mathrm{BF}_{4}\right]$ matrix at 85 K into any of the 344 , 311, or 229 nm absorptions results in bleaching of the parent vibrational band at 905 $\mathrm{cm}^{-1}$, and growth of a single product with absorptions at 870,929 , and $965 \mathrm{~cm}^{-1}$, Figure 2.3a. Broadband back-photolysis of the photoproduct with $\lambda_{\text {irr }}>400 \mathrm{~nm}$ results in complete reversion of the photoproduct to the parent permanganate complex, Figure 2.3b. Extended photolysis into the 525 nm transition results in formation of no observable photoproducts.

Figure 2.3: Photolysis of $\left[\mathrm{Et}_{3} \mathrm{OctN}\right]\left[\mathrm{MnO}_{4}\right]$ in $\left[\mathrm{Et}_{3} \mathrm{OctN}\right]\left[\mathrm{BF}_{4}\right]$ at 85 K . (a) $330 \pm 50 \mathrm{~nm}$ irradiated sample minus unphotolyzed sample. (b) Difference following $\lambda_{\text {irr }}>400 \mathrm{~nm}$ back photolysis of $330 \pm 50 \mathrm{~nm}$ irradiated sample.

The infrared spectrum of the observed photoproduct is not consistent with the formation of $\mathrm{MnO}_{2}^{-}$, that would be expected to exhibit only two vibrational modes in the metal-oxo stretching region. The observed spectrum is, however, consistent with $\mathrm{O}-\mathrm{O}$ bond formation to give the proposed $\mathrm{C}_{2 v}$ peroxo complex, $\mathrm{MnO}_{2}\left(\eta^{2}-\mathrm{O}_{2}\right)^{-}$. This species would be expected to exhibit an antisymmetric and symmetric $\mathrm{Mn}-\mathrm{O}$ vibrational absorption, assigned as the 965 and $929 \mathrm{~cm}^{-1}$ absorptions, respectively, as well as a peroxo vibrational mode in the 818-932 $\mathrm{cm}^{-1}$ region, ${ }^{24}$ observed at 870 $\mathrm{cm}^{-1}$. No new features in the superoxo vibrational region of $1100-1200 \mathrm{~cm}^{-1}$ are observed.

The lack of any new absorptions assignable to $\mathrm{MnO}_{2}{ }^{-},{ }^{25}$ as well as complete reversion to the parent permanganate complex upon $\lambda_{\mathrm{irr}}>400 \mathrm{~nm}$ back photolysis, indicates that no $\mathrm{O}_{2}$ loss is occurring under these conditions. This behavior may be suggestive of the peroxo complex formation being photochemical, with $\mathrm{O}_{2}$ loss from this species occurring thermally. An alternative explanation may be that $\mathrm{O}_{2}$ loss from $\mathrm{MnO}_{2}\left(\eta^{2}-\mathrm{O}_{2}\right)^{-}$occurs following secondary excitation, but that the barrier for $\mathrm{O}_{2}$ recapture by $\mathrm{MnO}_{2}{ }^{-}$is sufficiently low that this reaction occurs rapidly at 85 K . The reported independence of quantum yield with respect to photolysis intensity, however, makes such a multi-photon mechanism unlikely.

## Variable Temperature Solution Photolyses

In order to differentiate between possible photochemical and thermal decomposition pathways, we sought to reproduce the temperature and intensity dependence experiments performed by Zimmerman. Solution studies were
conducted under similar conditions as those used by Lee and coworkers, using an excess of sodium pyrophosphate in solution to coordinate the generated $\mathrm{MnO}_{2}{ }^{-}$and prevent deposition of a manganese oxide film on the walls of the photolysis vessel. Variable temperature photolysis experiments conducted with $\lambda_{\text {irr }}>590,550 \pm 50$, $532,525 \pm 50,450 \pm 50,>410,400 \pm 50$, and $330 \pm 75 \mathrm{~nm}$ from $5-75^{\circ} \mathrm{C}$ exhibited no appreciable thermal dependence on the rate of photodecomposition. The initial variable temperature experiments performed by Zimmerman utilized trypaflavine phosphorescence quenching to monitor $\mathrm{O}_{2}$ evolution from permanganate. This technique would be expected to provide a lower limit of detection than simple monitoring of UV-Vis as used in our experiments, however, even a modest thermal dependence would be anticipated to be measureable over a $70^{\circ} \mathrm{C}$ temperature window. Also conflicting with the work of Zimmerman, we saw no evidence of rate enhancement for the decomposition reaction when using photolysis wavelengths longer than 410 nm . These data suggest that there is no thermally dependent step in the photochemical decomposition reaction.

All energies are given in kcal $\mathrm{mol}^{-1}$. Vibrational frequencies are given in $\mathrm{cm}^{-1}$, values in parentheses are absorption intensities $\left(\mathrm{km} \mathrm{mol}^{-1}\right)$. Energy values for $\mathrm{MnO}_{2}{ }^{-}$include corrections for loss of ${ }^{3} \Sigma_{g}{ }^{-} \mathrm{O}_{2}$.

## Intensity Dependence Studies

The quantum yield of the photodecomposition reaction was measured as 5.5 $\times 10^{-3} \pm 2 \times 10^{-4}$ with $\lambda_{\text {irr }}=325 \pm 10 \mathrm{~nm}$. This value compares favorably to the value determined by Zimmerman of $4.8 \times 10^{-3} \pm 2 \times 10^{-4}$ with $\lambda_{\text {irr }}=313 \mathrm{~nm}$. Varying the intensity of the $\lambda_{\text {irr }}=325 \pm 10 \mathrm{~nm}$ photolysis of samples held at a constant $25^{\circ} \mathrm{C}$ gave no appreciable deviation in measured quantum yield. Plotting the rate of permanganate decomposition vs. photolysis intensity, Figure 2.5, exhibits a linear
relationship with a slope of $1.04 \pm 0.06$, indicating that the photodecomposition is a single photon reaction.

Figure 2.4: Typical spectral changes observed during variable-temperature solution photolyses. $\left[\mathrm{KMnO}_{4}\right]=2.25 \times 10^{-4} \mathrm{M},\left[\mathrm{HClO}_{4}\right]=0.115 \mathrm{M},\left[\mathrm{Na}_{4} \mathrm{P}_{2} \mathrm{O}_{7}\right]=4.78 \mathrm{x}$ $10^{-3} \mathrm{M}$.

Figure 2.5: Rate of $\mathrm{O}_{2}$ loss from permanganate solution vs. $325 \pm 10 \mathrm{~nm}$ photolysis intensity (einsteins $\mathrm{min}^{-1}$ ). Slope of best-fit line $=1.04 \pm 0.06 .\left[\mathrm{KMnO}_{4}\right]=2.25 \times 10^{-4}$

$$
\mathrm{M},\left[\mathrm{HClO}_{4}\right]=0.115 \mathrm{M},\left[\mathrm{Na}_{4} \mathrm{P}_{2} \mathrm{O}_{7}\right]=4.78 \times 10^{-3} \mathrm{M}
$$

The absence of any thermal or photolysis intensity dependence on the photodecomposition reaction implies that $\mathrm{O}_{2}$ loss occurs via single photon reaction. These observations are perplexing when compared to the results of the lowtemperature matrix photolysis where no evidence for $\mathrm{O}_{2}$ loss is found. These seemingly contradictory observations may be rationalized if the $\mathrm{MnO}_{2}\left(\eta^{2}-\mathrm{O}_{2}\right)^{-}$ product observed in the matrix is not an intermediate in the photodecomposition reaction, but rather the product of relaxation of an excited-state, vibrationally-hot,
$\left[\mathrm{MnO}_{2}\left(\mathrm{n}^{2}-\mathrm{O}_{2}\right)^{-}\right]$species that may also undergo an $\mathrm{O}_{2}$ loss relaxation pathway, Scheme 2.4.

Scheme 2.4: Proposed permanganate decomposition mechanism

In the excited state, loss of $\mathrm{O}_{2}$ from $\left[\mathrm{MnO}_{2}\left(\mathrm{n}^{2}-\mathrm{O}_{2}\right)\right]^{*}$ may be effectively barrierless, being enthalpically disfavored but entropically favored. This may explain the lack of any thermal dependence on the reaction. Under rigid-matrix conditions at 85 K where any generated $\mathrm{O}_{2}$ and $\mathrm{MnO}_{2}^{-}$would be held in close proximity, rapid recapture of $\mathrm{O}_{2}$ would be expected, explaining why no decomposition product is
 to be characterized under matrix conditions. In solution, the $\left[\mathrm{MnO}_{2}\left(\mathrm{n}^{2}-\mathrm{O}_{2}\right)\right]^{*}$ species may revert to the parent permanganate complex, relax to a vibrationally cool $\mathrm{MnO}_{2}\left(\mathrm{n}^{2}-\mathrm{O}_{2}\right)^{-}$species, or lose $\mathrm{O}_{2}$ to give $\mathrm{MnO}_{2}{ }^{-}$. Solvent cage effects may also facilitate rapid recombination of $\mathrm{MnO}_{2}^{-}$and $\mathrm{O}_{2}$ to give a vibrationally cool $\mathrm{MnO}_{2}\left(\eta^{2}-\right.$ $\mathrm{O}_{2}$ ) that may then revert to the parent permanganate complex or oxidize a substrate
in solution. Zimmerman noted that the quantum yield of the photodecomposition reaction increases dramatically with higher energy photolysis, suggesting that high energy photons may impart more vibrational energy to the $\left[\mathrm{MnO}_{2}\left(\eta^{2}-\mathrm{O}_{2}\right)\right]^{*}$ species and favor the $\mathrm{O}_{2}$ loss relaxation pathway.

## Photoluminescence Studies

The exact nature of the $\mathrm{O}_{2}$ evolved during the photodecomposition is unknown. Lee noted that there was no evidence for the involvement of singlet oxygen in their kinetics experiments, ${ }^{8}$ however, generation of singlet oxygen by transition metal peroxo compounds is well known. ${ }^{26,27}$ To clarify the nature of the generated $\mathrm{O}_{2}$, a sample of $\left[\mathrm{Et}_{3} \mathrm{OctN}\right]\left[\mathrm{MnO}_{4}\right]$ in $\mathrm{CH}_{3} \mathrm{CN}$ solution was monitored for singlet oxygen phosphorescence when subjected to 310 nm excitation. ${ }^{28}$ No emission could be detected under these conditions, suggesting that the $\mathrm{O}_{2}$ generated is being released in the ${ }^{3} \Sigma_{g}{ }^{-}$ground state.

## DFT Studies

To probe the mechanism and thermodynamics associated with the observed photochemical reaction in greater detail, a DFT investigation of the formation of $\mathrm{MnO}_{2}\left(\eta^{2}-\mathrm{O}_{2}\right)^{-}$was performed. Following the $\mathrm{O}-\mathrm{Mn}-\mathrm{O}$ bending mode of permanganate, Figure 2.6, results in a peroxo complex stationary point possessing $\mathrm{C}_{2 v}$ symmetry consistent with previous computational studies. ${ }^{9-11}$ This species is calculated to lie $41.9 \mathrm{kcal} \mathrm{mol}^{-1}$ higher in energy than the parent permanganate
complex. The transition state for the formation of this complex is placed 60.6 kcal $\mathrm{mol}^{-1}$ above the parent complex. Jahn-Teller distortion along the $\mathrm{O}-\mathrm{Mn}-\mathrm{O}$ bending mode results in $\mathrm{Mn}-\mathrm{O}$ bond elongation, such that the $\mathrm{O}-\mathrm{O}$ bond formation occurs in the $\mathrm{C}_{s}$ symmetry plane rather than through retention of $\mathrm{C}_{2 v}$ symmetry. The results of these calculations are summarized in Table 2.1. The calculated vibrational frequencies of $\mathrm{MnO}_{2}\left(\eta^{2}-\mathrm{O}_{2}\right)^{-}$reproduce the trends observed in the frozen-matrix photolysis studies lending support to the proposed structure of the photoproduct.

Figure 2.6: Calculated PES along the $\mathrm{O}-\mathrm{Mn}-\mathrm{O}$ bending mode.

The HOMO of $\mathrm{MnO}_{2}\left(\eta^{2}-\mathrm{O}_{2}\right)^{-}$is predominantly $\mathrm{O}-\mathrm{O}$ bonding and non-bonding metal $\mathrm{dz}^{2}$ in nature, Figure 2.7. The enhanced oxidative reactivity of this complex may be rationalized by the sterically unimpeded access to the $d z^{2}$ orbital in this geometry. The observed reversion of the peroxo complex to $\mathrm{MnO}_{4}{ }^{-}$upon $\lambda_{\text {irr }}>400$ nm back photolysis implies that MLCT must take place in this region of the spectrum.

SAOP excitation energies for $\mathrm{MnO}_{2}\left(\eta^{2}-\mathrm{O}_{2}\right)^{-}$show a number of transitions lower in energy relative to those of the parent permanganate complex, Table 2.2 and Figure 2.8. The lowest energy excitation of $\mathrm{MnO}_{2}\left(\eta^{2}-\mathrm{O}_{2}\right)^{-}$is calculated to be an intense $2 \mathrm{a} 2 \rightarrow 3 \mathrm{a} 2$ transition that can be described as charge transfer from the peroxo ligand to the manganese center. If the loss of $\mathrm{O}_{2}$ observed in solution did occur photochemically, this transition would provide a plausible trigger for $\mathrm{O}_{2}$ loss and concurrent two-electron reduction of $\mathrm{Mn}(\mathrm{V}) \mathrm{MnO}_{2}\left(\eta^{2}-\mathrm{O}_{2}\right)^{-}$to $\mathrm{Mn}(\mathrm{III}) \mathrm{MnO}_{2}^{-}$. The second and third lowest energy transitions, by contrast, are from the 14a1 orbital to the 7 b 1 and 15 a 1 molecular orbitals and are MLCT in character. MLCT to the peroxo ligand would be responsible for the reduction of the peroxo ligand to yield the parent permanganate complex.

## Conclusions

The metastable $\mathrm{Mn}(\mathrm{V})$ peroxo complex, $\mathrm{MnO}_{2}\left(\eta^{2}-\mathrm{O}_{2}\right)^{-}$, has been observed as a product in the photolysis of the permanganate anion. Formally the product of photochemical reductive elimination of a peroxo ligand, this is the first experimental characterization of the long-lived photoproduct speculated in previous experimental ${ }^{8}$ and computational ${ }^{9-11}$ studies. The absence of any species assignable as $\mathrm{MnO}_{2}{ }^{-}$in our 85 K photolysis experiments, the determination of a single photon requirement for decomposition, lack of any measureable temperature dependence, and increasing quantum yield with higher energy photolysis is highly suggestive of $\mathrm{O}_{2}$ loss occurring through a vibrationally hot, excited state $\left[\mathrm{MnO}_{2}\left(\eta^{2}-\mathrm{O}_{2}\right)^{-}\right]^{*}$ species as opposed to $\mathrm{O}_{2}$ loss from the observed $\mathrm{MnO}_{2}\left(\eta^{2}-\mathrm{O}_{2}\right)^{-}$photoproduct.

## Experimental

$\left[\mathrm{Et}_{3} \mathrm{OctN}\right]\left[\mathrm{MnO}_{4}\right]$ was prepared by adding an excess of $\left[\mathrm{Et}_{3} \mathrm{OctN}\right]\left[\mathrm{BF}_{4}\right]$ to an aqueous potassium permanganate solution. After twenty minutes of vigorous mixing at room temperature, the solution was extracted with a minimal volume cold methylene chloride. The extracts were dried over $\mathrm{MgSO}_{4}$ and solvent removed on a rotary evaporator. $\mathrm{KMn}^{18} \mathrm{O}_{4}$ was prepared by the literature procedure. ${ }^{29-31} 98 \%$ enriched $\mathrm{H}_{2}{ }^{18} \mathrm{O}$ was supplied by Medical Isotopes, Inc. The apparatus and methods for matrix photochemistry have been reported elsewhere. ${ }^{32}$ Variable temperature photolysis experiments were performed in a water-jacketed pyrex flask with temperatures being held to within $\pm 0.2 \mathrm{~K}$ by a circulating bath. Aliquots of the photolyzed solution were periodically removed and equilibrated to $25^{\circ} \mathrm{C}$ prior to
measuring the UV-Vis spectrum, referencing against a dark sample kept at the same temperature to account for thermal decomposition. Photon fluxes were determined by ferrioxalate actinometry. Photoluminescence spectra were measured with a Horiba Jobin-Yvon Nanolog equipped with an $\mathrm{LN}_{2}$ cooled InGaAs detector.

All DFT calculations were performed in the Amsterdam Density Functional (ADF2013.01) program. ${ }^{33-35}$ Electronic configurations of atoms were described by an all-electron quadruple-ऽ Slater-type orbital basis set modified by four polarization functions (QZ4P STO). ${ }^{36}$ Geometry optimizations and vibrational frequency calculations were performed using the dispersion corrected meta-GGA TPSSD3(BJ). ${ }^{37-39}$ Vertical electronic excitation energies were computed the statistical average of orbital potentials (SAOP) model. ${ }^{40,41}$

## Chapter 3: Revisiting the Photochemistry of Vaska's $\mathbf{O}_{2}$ Complex: Competitive Reductive and Non-Reductive Elimination Reactions.

Submitted for review and publication: W.A. Thornley, T.E. Bitterwolf Angew. Chem. Int. Ed. Engl. 2016.

#### Abstract

Low-temperature frozen matrix and solution photochemistry experiments on the dioxygen adduct of Vaska's complex, Ir"II $\mathrm{Cl}(\mathrm{CO}) \mathrm{O}_{2}\left[P\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$, reveal that a competitive non-reductive elimination of $\mathrm{CO}_{2}$ to yield $\operatorname{Ir}{ }^{\prime \prime \prime} \mathrm{Cl}(\mathrm{O})\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$ competes with the long-known photochemical reductive elimination of $\mathrm{O}_{2}$ yielding Ir'Cl(CO) $\left[P\left(C_{6} H_{5}\right)_{3}\right]_{2}$. Photochemical experiments conducted in solution at room temperature also yield $\mathrm{OPPh}_{3}$, arising from a secondary reaction of the $\mathrm{CO}_{2}$ loss iridium species. DFT computations suggest that elimination of $\mathrm{CO}_{2}$ from Vaska's $\mathrm{O}_{2}$ complex is a thermodynamically favored photothermal side reaction, while $\mathrm{O}_{2}$ ejection is favored through a purely photochemical reaction pathway.

Vaska's complex is an iconic molecule in organometallic chemistry, having shaped the understanding of oxidative addition and reductive elimination reactions fundamental to homogeneous catalysis through its ability to reversibly add substrates to form stable 18-electron $\mathrm{Ir}^{1 I I}$ complexes, Scheme 3.1. ${ }^{1-9}$ One of these reactions, the addition of oxygen to Vaska's complex to yield $\operatorname{IrCl}(\mathrm{CO}) \mathrm{O}_{2}\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$, is particularly noteworthy as this dioxygen adduct served as an early model for
molecular oxygen transport. ${ }^{10-19}$ The reverse of this reaction, elimination of oxygen to yield 16-electron $\operatorname{IrCl}(\mathrm{CO})\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$ and $\mathrm{O}_{2}$, is known to occur both thermally and photochemically, with the photochemical elimination reportedly being robust and able to be cycled without decomposition. ${ }^{20}$ Following 308 nm photolysis of Vaska's $\mathrm{O}_{2}$ adduct, the eliminated oxygen is produced in both the ${ }^{1} \Delta_{\mathrm{g}}$ and ${ }^{3} \Sigma_{\mathrm{g}}$ - electronic states with quantum yields of 0.03 and 0.40 , respectively, indicating that reductive elimination occurs directly through an electronically excited singlet state, as well as the result of an intersystem crossing (ISC). ${ }^{21}$

Scheme 3.1: Generalized oxidative addition and reductive elimination reactions of Vaska's complex. $\mathrm{XY}=\mathrm{H}_{2}, \mathrm{SO}_{2}, \mathrm{HCl}, \mathrm{O}_{2}, \mathrm{BF}_{3}$, halogens, etc...

Recent work in our laboratory has centered upon the photochemistry of transition metal oxides and nitrides in low-temperature frozen matrices where we've reported instances of reversible four and six-electron reductive elimination and oxidative addition reactions. ${ }^{22,23}$ We decided to direct our attention towards this archetypal photochemical oxygen elimination from Vaska's complex in hopes that an intermediate prior to $\mathrm{O}_{2}$ ejection (i.e. metal superoxide or $\eta^{1}-\mathrm{O}_{2}$ ) or a metastable geometrical isomer of $\operatorname{lrCl}(\mathrm{CO})\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$ following $\mathrm{O}_{2}$ ejection would be directly observed at cryogenic temperatures, further developing upon the mechanistic model
for this class of reactions. The results of these experiments did not yield any evidence for non-concerted $\mathrm{O}_{2}$ reductive elimination from this molecule, but did result in the surprising observation of photochemical elimination of $\mathrm{CO}_{2}$.

In poly(vinyl chloride) (PVC) matrices at 85 K , photolysis at wavelengths beginning with $500 \pm 50 \mathrm{~nm}$ result in bleaching of the parent $\operatorname{IrCl}(\mathrm{CO}) \mathrm{O}_{2}\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$ carbonyl ( $2014 \mathrm{~cm}^{-1}$ ), triphenylphosphine (1484, 1436, and $1104 \mathrm{~cm}^{-1}$ ), and peroxo (855 $\mathrm{cm}^{-1}$ ) vibrational modes with concomitant growth of photoproduct absorptions at $1958,1478,1431$, and $1096 \mathrm{~cm}^{-1}$, corresponding to the $\mathrm{O}_{2}$ elimination product, $\operatorname{Ir}^{\prime} \mathrm{Cl}(\mathrm{CO})\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$, and a strong absorption at $2335 \mathrm{~cm}^{-1}$ belonging to matrixtrapped $\mathrm{CO}_{2}$. Isotopic substitution with ${ }^{13} \mathrm{CO}$ results in expected infrared shifts of the product $\operatorname{Ir} \mathrm{Cl}\left({ }^{13} \mathrm{CO}\right)\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$ carbonyl and eliminated ${ }^{13} \mathrm{CO}_{2}$ absorption bands to $1911 \mathrm{~cm}^{-1}$ and $2269 \mathrm{~cm}^{-1}$, respectively, while positions of features arising from changes to the peroxo and triphenylphosphine ligands remain identical to the natural abundance CO experiment. Photolysis at shorter wavelengths $(450 \pm 50 \mathrm{~nm}, 400 \pm$ 50 nm , and $330 \pm 70 \mathrm{~nm}$ ) increases the extent of this reaction, but does not result in any changes to the observed photoproducts. Increasing the duration of photolysis was found to increase the intensity of the $\mathrm{CO}_{2}$ product absorption band relative to the $\operatorname{lrCl}(\mathrm{CO})\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$ product absorption.

Figure 3.1: Photolysis of $\operatorname{IrCl}(\mathrm{CO}) \mathrm{O}_{2}\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$ in PVC matrix at 85 K . Difference following 10 minutes $400 \pm 50 \mathrm{~nm}$ irradiation subtracted from unphotolyzed sample (black trace). Results of photolysis of the ${ }^{13} \mathrm{CO}$ isotopomer presented as grey trace ( $\Delta$ Abs scaled $\sim 3.5 x$ to match natural abundance photolysis).

No absorption bands directly assignable to an organometallic reaction product resulting from $\mathrm{CO}_{2}$ elimination, putatively $\operatorname{lr}{ }^{\text {III }} \mathrm{CIO}\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$, are observed. This absence isn't necessarily surprising as the $\mathrm{Ir}=\mathrm{O}$ vibration of a transIr ${ }^{I I I} \mathrm{CIO}\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$ species would be anticipated to be very weak due to the minor net
change in dipole associated with such a vibration. Interestingly, while triphenylphosphine oxide, $\mathrm{OPPh}_{3}$, may be expected to competitively eliminate with $\mathrm{CO}_{2}$ following photochemical $\mathrm{O}-\mathrm{O}$ bond activation, no vibrational mode assignable to the $\mathrm{P}=\mathrm{O}$ stretch of $\mathrm{OPPh}_{3}$, nor a corresponding Ir carbonyl photoproduct, are observed, indicating preferential elimination of $\mathrm{CO}_{2}$ under these conditions.

Performing short duration (5 minutes) photolyses of $\operatorname{IrCl}(\mathrm{CO}) \mathrm{O}_{2}\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$ in air-free $\mathrm{CH}_{2} \mathrm{Cl}_{2}$ solution in a gas-tight FTIR sample cell at room temperature yields the same products observed in low-temperature matrix experiments, however, the ratio of the $\mathrm{CO}_{2}$ antisymmetric vibrational mode to the $\operatorname{IrCl}(\mathrm{CO})\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$ carbonyl vibrational mode absorption areas changes from 1:5.5 in PVC at 85 K to 1:10.4 in $\mathrm{CH}_{2} \mathrm{Cl}_{2}$ at 298 K . This result, in addition to the observation that extending photolysis duration in frozen-matrix experiments favors the $\mathrm{CO}_{2}$ elimination reaction, suggests that photoejected $\mathrm{O}_{2}$ and $\operatorname{IrCl}(\mathrm{CO})\left[\mathrm{P}_{\left.\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2} \text { may undergo recombination and }}^{\text {m }}\right.$ subsequent photolysis, resulting in increasing the extent of an irreversible $\mathrm{CO}_{2}$ elimination process relative to that of the reversible $\mathrm{O}_{2}$ elimination photoreaction. While this recombination would be expected to occur thermally at room temperature, the fact that this appears to happen at cryogenic temperature is somewhat unexpected. We propose that at 85 K , this recombination is facilitated by a mechanism taking place through a photogenerated long-lived triplet state of $\operatorname{IrCl}(\mathrm{CO})\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$ which may undergo spin-allowed addition of $\mathrm{O}_{2}$ at cryogenic temperatures. Consistent with this argument, a time-resolved IR study conducted on Vaska's complex following 308 nm excitation exhibited evidence for a long-lived electronically excited-state of $\operatorname{IrCl}(\mathrm{CO})\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$, which may be this proposed triplet
state species. ${ }^{24}$ Further promoting this $\mathrm{O}_{2}$ addition reaction is the fact that photoliberated $\mathrm{O}_{2}$ and $\operatorname{IrCl}(\mathrm{CO})\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$ are held in close proximity, poised for recapture, due to the frozen matrix conditions these experiments are performed in.

Previous solution experiments reported that photolysis of $\operatorname{IrCl}(\mathrm{CO})\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$ in benzene under $\mathrm{O}_{2}$ purge results in generation of a dark green solution with $\mathrm{OPPh}_{3}$ being identified as a by-product by FTIR..$^{20}$ In order to expand upon the nature of this photoreaction, we replicated this study on the solution photochemistry of $\operatorname{lrCl}(\mathrm{CO}) \mathrm{O}_{2}\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$ in toluene and $\mathrm{CD}_{2} \mathrm{Cl}_{2}$ solutions under pressures of $\mathrm{O}_{2}$. In $\mathrm{CD}_{2} \mathrm{Cl}_{2}$ solutions under $\sim 7 \mathrm{PSI} \mathrm{O}_{2}, 350 \pm 70 \mathrm{~nm}$ irradiation of $\operatorname{IrCl}\left({ }^{13} \mathrm{CO}\right) \mathrm{O}_{2}\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$ yields intensely emerald green solutions $\left(\lambda_{\max }=604 \mathrm{~nm}\right)$ that demonstrate remarkably clean conversion of the parent molecule to $\mathrm{OPPh}_{3}$ and ${ }^{13} \mathrm{CO}_{2}$ by ${ }^{31} \mathrm{P},{ }^{13} \mathrm{C}$, and ${ }^{1} \mathrm{H}$ NMR. No paramagnetic species were apparent by EPR in $\mathrm{CH}_{2} \mathrm{Cl}_{2}$ solutions at room temperature, and we've been unable to grow crystals satisfactory for diffraction study of the green product of this reaction, leaving the ultimate fate of the iridium unclear. As low-temperature photolysis experiments exhibited preferential elimination of $\mathrm{CO}_{2}$ over $\mathrm{OPPh}_{3}$, the formation of the $\mathrm{OPPh}_{3}$ observed in solution experiments is attributed as the result of secondary reaction of the initially formed $\mathrm{CO}_{2}$ elimination photoproduct, $\operatorname{Ir}{ }^{\text {III }} \mathrm{ClO}\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$.

Figure 3.2: SAOP calculated frontier orbitals of $\operatorname{IrCl}(\mathrm{CO}) \mathrm{O}_{2}\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$.

The question as to how $\mathrm{O}-\mathrm{O}$ bond activation occurs to yield $\mathrm{CO}_{2}$ is seemingly paradoxical. One of the more surprising observations from these low-temperature frozen matrix photolyses is that the $\mathrm{O}_{2}$ and $\mathrm{CO}_{2}$ elimination reactions are in apparent competition at all photochemically active wavelengths. The elimination of $\mathrm{O}_{2}$ from the parent Ir ${ }^{\prime I I}$ complex to yield $\mathrm{O}_{2}$ and trans- $\mathrm{Ir}^{\prime} \mathrm{Cl}(\mathrm{CO})\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$ would be anticipated to be the result of an excitation $\operatorname{Ir} \leftarrow \mathrm{O}_{2}$ LMCT in character, however, cleavage of the $\mathrm{O}-\mathrm{O}$ bond required to yield $\mathrm{CO}_{2}$ is suggestive of a photointermediate or transition state resembling $\left.\operatorname{Ir}^{v} \mathrm{Cl}(\mathrm{CO})(\mathrm{O})_{2}\left[\mathrm{P}_{( } \mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$, implying the product of $\mathrm{O}_{2} \leftarrow$ Ir MLCT
excitation. In order to clarify how this transformation occurs, we performed a DFT examination on this reaction.

The frontier orbitals of $\operatorname{IrCl}(\mathrm{CO}) \mathrm{O}_{2}\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$ are presented in Figure 3.2. The HOMO is dominated by an $\mathrm{O}_{2} \pi^{*}$ molecular orbital, while the LUMO is composed predominantly of $\mathrm{Ir}_{\mathrm{d}_{22-y}}, \mathrm{~d}_{22}$, and $\mathrm{Cl} \mathrm{p}_{\mathrm{y}}$ atomic orbitals. TD-DFT computations suggest that the electronic transitions in the region of the observed photochemistry are dominated by LUMO $\leftarrow$ HOMO excitations which may be characterized as being $\mathrm{Ir} \leftarrow \mathrm{O}_{2}$ LMCT, fully consistent with photochemical $\mathrm{O}_{2}$ ejection. Optimizing the geometries for the first few of these excited states yields structural changes that would be anticipated for $\operatorname{Ir} \leftarrow \mathrm{O}_{2}$ LMCT, chiefly increasing Ir $-\mathrm{O}_{2}$ bond lengths and a decrease in the $\mathrm{O}-\mathrm{O}$ bond length. These results, suggesting purely $\mathrm{O}_{2}$ elimination photochemistry, are particularly confounding with respect to our experimental results which demonstrates competitive $\mathrm{O}_{2}$ and $\mathrm{CO}_{2}$ elimination photochemistry at all photochemically active wavelengths. What we then propose is a mechanism by which O-O bond activation occurs photothermally as the result of vibrational cooling of an electronically excited $\operatorname{IrCl}(\mathrm{CO}) \mathrm{O}_{2}\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}^{*}$, as opposed to occurring directly in an excited state. This explanation may rationalize how $\mathrm{O}-\mathrm{O}$ bond cleavage is observed following an LMCT excitation from the $\mathrm{O}_{2}$ ligand.

To better understand the energetics and intermediate species that may be involved in a photothermal $\mathrm{O}_{2}$ activation mechanism, we scanned the potential energy surface (PES) of $\operatorname{IrCl}(\mathrm{CO}) \mathrm{O}_{2}\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$ along the $\mathrm{O}-\mathrm{O}$ vibrational mode. The results of these calculations are presented in Scheme 3.2. A transition state geometry corresponding to $\mathrm{O}-\mathrm{O}$ bond cleavage and $\mathrm{O}-\mathrm{CO}$ bond formation was
found to lie $52.4 \mathrm{kcal} \mathrm{mol}^{-1}$ higher in energy relative to the parent peroxo complex, which ultimately yields a stationary point corresponding to a $\mathrm{CO}_{2}$ complex 25.3 kcal $\mathrm{mol}^{-1}$ lower in energy than the parent complex. From the $\mathrm{CO}_{2}$ complex, a relatively small barrier of $5.6 \mathrm{kcal} \mathrm{mol}^{-1}$ is associated with the dissociation of the $\mathrm{Ir}-\mathrm{CO}_{2}$ bond to yield of $\operatorname{IrCl}(\mathrm{O})\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$ and $\mathrm{CO}_{2}$, resulting in a net change of Gibbs energy to $33.5 \mathrm{kcal} \mathrm{mol}^{-1}$ relative to the parent molecule. Alternatively, if an intersystem crossing (ISC) occurs following the formation of the O-CO bond, which may be promoted by both the photochemical conditions under which this reaction is performed as well as spin-orbit coupling with Ir , the expulsion of $\mathrm{CO}_{2}$ from the iridium complex is calculated to be effectively barrierless, and yields a triplet state trans$\operatorname{IrClO}\left[P\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2} 13.7 \mathrm{kcal} \mathrm{mol}^{-1}$ lower in energy relative to the singlet state isomer.

Additional matrix photolysis experiments we've conducted on the $\mathrm{H}_{2}, \mathrm{D}_{2}$, and HCl adducts of Vaska's complex yielded evidence for only clean reductive elimination of the adduct and reversion to $\operatorname{lrCl}(\mathrm{CO})\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$. The absence of any secondary products in these photolyses demonstrates that a competing photothermal reductive elimination pathway may not be present for all adducts of Vaska's complex, and that the $\mathrm{O}_{2}$ complex may be an exceptional case as the elimination of $\mathrm{CO}_{2}$ as reaction product offers a large thermodynamic driving force. Regardless, the results of frozen-matrix and solution photochemistry experiments demonstrate an unreported, yet significant, competitive elimination pathway of $\mathrm{CO}_{2}$ in one of the archetypal photochemical reactions in organometallic photochemistry. While detailed time-resolved studies will be necessary to elucidate the mechanism and energies involved with this transformation, results from DFT computations
suggest the formation does not occur directly in an excited state of $\operatorname{IrCl}(\mathrm{CO}) \mathrm{O}_{2}\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$, but rather as the result of vibrational cooling of a vibrationally hot $\operatorname{IrCl}(\mathrm{CO}) \mathrm{O}_{2}\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}{ }^{*}$ species.

Reaction Coordinate
Scheme 3.2: Reaction coordinate for the elimination of $\mathrm{CO}_{2}$ from

$$
\operatorname{IrCl}(\mathrm{CO}) \mathrm{O}_{2}\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}
$$

## Experimental

$\operatorname{IrCl}(\mathrm{CO})\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$ was prepared by literature procedure. ${ }^{1} \operatorname{IrCl}\left({ }^{13} \mathrm{CO}\right)\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$ was synthesized by placing 120 mg of $\operatorname{IrCl}(\mathrm{CO})\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$ in methylene chloride under a 25-fold excess of ${ }^{13} \mathrm{CO}$ (Cambridge Isotope Laboratories) in an Ace pressure tube and irradiating with $350 \pm 70 \mathrm{~nm}$ light for 12 hours. The solution was then depressurized and placed under a rapid stream of purified Ar while photolysis continued for another 6 hours to convert $\operatorname{IrCl}\left({ }^{13} \mathrm{CO}\right)_{2}\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$ to $\operatorname{IrCl}\left({ }^{13} \mathrm{CO}\right)\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$,
achieving $\sim 95 \%{ }^{13} \mathrm{CO}$ enrichment by FTIR. The apparatus and methods for matrix photochemistry have been reported elsewhere. ${ }^{25}$

All DFT calculations were performed in the Amsterdam Density Functional (ADF2014.10) program. ${ }^{26-28}$ Electronic configurations of atoms were described by an all-electron triple-乙 Slater-type orbital basis set modified by a polarization functions (TZP STO). ${ }^{29}$ Geometry optimizations and vibrational frequency calculations were performed using the GGA functional of $B^{3} e^{30}$ and Perdew ${ }^{31,32}$ with a scalar relativistic correction within the Zeroth Order Regular Approximation (ZORA). ${ }^{33,34}$. Electronic excitation energies were computed using statistical average of orbital potentials (SAOP) model. ${ }^{35,36}$

#### Abstract

The $[\mathrm{FeFe}]-h y d r o g e n a s e ~ m o d e l ~ c o m p l e x e s ~(~ \mu-p d t)\left[F e(C O)_{3}\right]_{2}, \quad(\mu-$ edt) $\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}$, and $(\mu-\mathrm{mdt})\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}$, where pdt $=1,3$-propanedithiolate, edt $=1,2-$ ethanedithiolate, and mdt = methanedithiolate, undergo wavelength dependent photodecarbonylation in hydrocarbon matrices at 85 K resulting in multiple decarbonylation isomers. As previously reported in time-resolved solution photolysis experiments, the major photoproduct is attributed to a basal carbonyl loss species. Apical carbonyl loss isomers are also generated and may undergo secondary photolysis resulting in $\beta$-hydride activation of the alkyl dithiolate bridge as well as formation of bridging carbonyl isomers. For $(\mu-b d t)\left[F e(C O)_{3}\right]_{2}, \quad(b d t=1,2-$ benzenedithiolate), apical photodecarbonylation results in generation of a $10 \pi$ electron aromatic $\mathrm{FeS}_{2} \mathrm{C}_{6} \mathrm{H}_{4}$ metallacycle that coordinates the remaining iron through an $\eta^{5}$ mode.

The ability of the hydrogenase family of enzymes to reversibly catalyze the activation of hydrogen has drawn considerable interest as a model for renewable energy storage ${ }^{[1-9]}$ The organometallic active site of the [FeFe]-hydrogenase enzyme
is composed of a dithiolate-bridged diiron core coordinated by CO and $\mathrm{CN}^{-}$ligands, and a cysteinyl ligand that links the diiron active site to an electron transport network composed of $\left[\mathrm{Fe}_{4} \mathrm{~S}_{4}\right]$ cubanes, Scheme 4.1a. ${ }^{[10,11]}$ In the oxidized form, a CO ligand serves as a bridge between the diiron center and reverts to a semi-bridging or terminal coordination mode in the reduced form. ${ }^{[12]}$ Crystallographic evidence indicates that the dithiolate bridgehead may be composed of a $\mathrm{CH}_{2}, \mathrm{O}$, or NH functionality, though the chemistry of functional model complexes seem to indicate that this bridgehead is most likely an NH functionality that serves to act as proton relay to the metal. ${ }^{[6,9,13-15]}$ Extensive synthetic strategies have been developed for the preparation of [FeFe]-hydrogenase model complexes since the elucidation of the active site structure. ${ }^{[16-22]}$

Scheme 4.1: Proposed active site of the [FeFe]-Hydrogenase enzyme (a), ( $\mu$ -$\mathrm{pdt})\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}(\mathrm{~b}),(\mu-\mathrm{edt})\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}(\mathrm{c}),(\mu-\mathrm{mdt})\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}(\mathrm{~d})$, and $(\mu-\mathrm{bdt})\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}(\mathrm{e})$

As a means to study the bonding and reactivity of the hydrogenase active site and model complexes, numerous photochemical experiments have been performed in low-temperature matrices and in solution. The photochemistry of the CO-inhibited form of Clostridium pasteurianum has been studied at temperatures from 6-30 K by FTIR and EPR. ${ }^{[23-25]}$ It was found that photolysis of this species at low temperature gave rise to two CO loss products, one having an identical infrared spectrum to the oxidized form of Clostridium pasteurianum that reverts to the CO-inhibited form at temperatures > 150 K . The second photoproduct was found to lose the characteristic bridging carbonyl functionality and revert at temperatures $>80 \mathrm{~K}$.

In solution, the photochemistry of the $(\mu-\mathrm{pdt})\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}(\mathrm{pdt}=1,3-$ propanedithiolate) [FeFe]-hydrogenase model complex, Scheme 4.1b, has been the subject of several investigations. Under steady-state photolysis in coordinating and non-coordinating solvents, partially reversible substitution of CO by solvent to give $(\mu-\mathrm{pdt}) \mathrm{Fe}_{2}(\mathrm{CO})_{5}(\mathrm{sol})$ has been reported. ${ }^{[26,27]}$ On the ultrafast timescale, a CO loss species possessing solely terminal carbonyls is generated that is generally assigned to a basal CO loss species with a weakly coordinated solvent molecule occupying the vacant metal site. ${ }^{[28-30]}$ This CO loss species undergoes recapture of CO following bimolecular kinetics on the microsecond timescale, though some evidence for growth of a dimeric species has been observed on longer timescales. ${ }^{[29]}$ Multidimensional ultrafast IR experiments on the CO loss product support the formation of only a single pentacarbonyl species, and in contrast to other studies, suggest that CO loss and solvent coordination is occurring at an apical Fe
coordination site based on anisotropic measurements and DFT simulations. ${ }^{[31]} \mathrm{A}$ generalized scheme of the observed photochemistry is presented in Scheme 4.2.

Scheme 4.2: Solution photochemistry of ( $\mu$-pdt) $\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}$

To gain a clearer understanding of the structures of the photoproducts, effect of photolysis wavelengths, and the possibility of multi-step, multi-photon reactions that may not be observed in transient pump-probe experiments, we've recently begun exploring the photochemistry of [FeFe]-hydrogenase model complexes in low-temperature frozen matrices with characterization being performed by FTIR. Herein, we report the initial findings of these experiments, investigating the steric and electronic effects of the dithiolate bridge on the decarbonylative photochemistry of these model complexes.

The electronic spectra of the [FeFe]-hydrogenase model complexes studied, Scheme 4.1b-e, are markedly similar. Their most notable features are a strong transition at ca. 335 nm and a broad, weak absorption centered at 465 nm having a
tail extending to ca. 650 nm , Figure 4.1. To better understand the nature of the electronic transitions involved in the UV-Vis spectrum and how they may influence the photochemistry of these complexes, time-dependent density functional theory (TD-DFT) modelling of the electronic spectrum of $(\mu-\mathrm{pdt})\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}$ using the statistical average of orbital potentials (SAOP) model was performed. ${ }^{[32,33]}$ Results of these computations, summarized in Table 4.1 and Figure 4.2, give excitation energies that are slightly underestimated, but in overall excellent agreement with the experimentally measured spectrum. The computed transitions suggest that the broad, low-energy feature of this spectrum is composed of several transitions from molecular orbitals that are dominated by bonding interactions between $\mathrm{Fe}_{2 \mathrm{~g}}$ and sulfur p -orbitals or the $\mathrm{Fe}-\mathrm{Fe} \sigma$ bond into an orbital that is $\mathrm{Fe}-\mathrm{Fe} \sigma^{*}$ in character. Consistent with this model, evidence from ultrafast 532 nm pump-probe experiments and resonance-Raman experiments suggest elongation of the $\mathrm{Fe}-\mathrm{Fe}$ bond when subjected to excitation in this region. ${ }^{[30,34]}$ Transitions in the region of the intense absorption at 335 nm are distinctly metal-to-ligand charge-transfer (MLCT) in character, comprised of transitions from the Fe-Fe $\sigma$ bond orbital into orbitals that are largely $\mathrm{CO} \pi^{*}$ and sulfur p-orbital in nature. Excitation into these $\mathrm{CO} \pi^{*}$ orbitals would be expected to result in disassociation of CO as is observed in previously reported photochemical experiments. We should note that this interpretation comes in contrast to a previous study that assigned the intense 335 nm absorption to a FeFe $\sigma^{\star} \leftarrow \mathrm{Fe}$-Fe $\sigma$ transition, but offers a similar interpretation of the low-energy feature. ${ }^{[34]}$

## Photolysis of ( $\mu$-pdt)[Fe(CO) $]_{3}$ at 85 K in Hydrocarbon Matrices

Photolysis into the low energy electronic transitions of $\left(\mu\right.$-pdt) $\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}$ with $\lambda_{\text {irr }}=450 \pm 70 \mathrm{~nm}$ light in Nujol glass at 85 K results in bleaching of the parent vibrational bands and growth of new absorptions at 2132, 2081, 2052, 1998, 1982, 1973, 1961, and $1942 \mathrm{~cm}^{-1}$, Figure 4.3a. The feature at $2132 \mathrm{~cm}^{-1}$ corresponds to "free" CO, while the product bands at 2052, 1998, 1973, and $1942 \mathrm{~cm}^{-1}$ are in excellent agreement with those observed in heptane solution TRIR experiments. ${ }^{[28,29]}$ Interestingly, the product bands at 2081, 2041, 1982, and $1961 \mathrm{~cm}^{-1}$ are unique to our low-temperature matrix photolysis experiments and belong to a species having no direct analogue in the reported transient solution studies. At higher energy photolysis wavelengths, $\lambda_{\mathrm{irr}}=330 \pm 70 \mathrm{~nm}$, Figure 4.3 b , an additional species exhibiting vibrational modes at 2025, 2012, and $1843 \mathrm{~cm}^{-1}$ appears. Annealing the photoproducts in hydrocarbon glass to 135 K and refreezing to 85 K results in clean reversion of the carbonyl loss isomers to the parent hexacarbonyl complex. Back photolysis of the $\lambda_{\text {irr }}=330 \pm 70 \mathrm{~nm}$ sample at long wavelengths, $\lambda_{\mathrm{irr}}=550 \pm 70 \mathrm{~nm}$, also results in recapture of CO and reformation of the parent complex.

Figure 4.3. Photolysis of $(\mu$-pdt $)\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}$ in glassy Nujol at 85 K . (a) 120 minute $450 \pm 70 \mathrm{~nm}$ irradiated sample minus unphotolyzed sample. (b) Difference following 90 minutes $330 \pm 70 \mathrm{~nm}$ irradiation

The additional product bands observed in our low-temperature matrix photolysis experiments that are absent in transient solution studies may be attributed to multi-photon reactions resulting in rearrangement of a primary photoproduct. As the matrix photolyses are performed under steady-state photolytic conditions, multi-step and multi-photon reactions like this are possible, providing a route to products not observed in transient pump-probe experiments. Varying photolysis duration between 10 and 300 minutes results in no observable change in the relative ratios of the photoproducts, suggesting that a photoequilibrium between the carbonyl loss isomers is rapidly established under steady-state photolysis conditions.

Of the unique product bands observed in the low-temperature photochemistry experiments, the two most noteworthy features are the vibrational bands at $2081 \mathrm{~cm}^{-1}$, which is shifted to higher energy relative to the parent hexacarbonyl complex, implying formal oxidation of the photoproduct, and the band at $1843 \mathrm{~cm}^{-1}$ that lies within the bridging carbonyl stretching region. As the $2081 \mathrm{~cm}^{-}$ ${ }^{1}$ band could conceivably be attributed to $\mathrm{C}-\mathrm{H}$ bond activation of the Nujol matrix following coordination of a vacant metal site, the sample was also photolyzed in Fluorolube oil (chlorotrifluoroethylene polymer). Photolysis in Fluorolube oil leads to generation of an analogous species, suggesting that this product is the result of an intramolecular rearrangement and not engendered through reaction with the matrix material. In order to clarify the structures of and relationships between possible CO loss isomers observed in the matrix photochemistry, we carried out a DFT investigation on the isomers of $(\mu-\mathrm{pdt}) \mathrm{Fe}_{2}(\mathrm{CO})_{5}$, Scheme 4.3.

$\Delta G \stackrel{C}{=} 1.1$

Scheme 4.3: TZP/TPSS-D3(BJ) DFT energies $\left(\mathrm{kcal} \mathrm{mol}^{-1}\right)$ of the nine lowest energy isomers of $(\mu-\mathrm{pdt})\left[\mathrm{Fe}_{2}(\mathrm{CO})_{5}\right]$.

Surprisingly, the lowest energy isomer of $(\mu-\mathrm{pdt}) \mathrm{Fe}_{2}(\mathrm{CO})_{5}$ was found to be a triplet state species possessing $\mathrm{C}_{\mathrm{s}}$ symmetry with the carbonyl groups of the unsaturated iron positioned within the $\mathrm{C}_{\mathrm{s}}$ plane of the molecule, 4.3a. While we have no direct experimental evidence to suggest the presence of an open-shell decarbonylated species, and recognize the limitations of DFT when applied to openshell transition metal complexes, ${ }^{[35]}$ we include this result as the role of low-lying open-shell intermediates in the reaction chemistry of these models may warrant further investigation.

Of the closed-shell stationary points of $(\mu-\mathrm{pdt}) \mathrm{Fe}_{2}(\mathrm{CO})_{5}$, the lowest energy isomers were found to posses a bridging carbonyl group and exhibit either agostic, 4.3b, or sigma, 4.3c, interactions between a vacant apical coordination site and a $\beta$ hydrogen of the propanedithiolate bridge. These agostic or sigma interactions stabilize the bridging carbonyl geometry by 1.7 and $1.6 \mathrm{kcal} \mathrm{mol}^{-1}$, respectively, relative to the bridging carbonyl geometry that possesses no such interactions, 4.3f. In agreement with previous studies, ${ }^{[28]}$ two all terminal carbonyl CO loss species were found possessing vacant basal, 4.3e, and apical, 4.3i, coordination sites and lay 2.4 and $7.3 \mathrm{kcal} \mathrm{mol}^{-1}$ higher in energy than the triplet state global minima respectively. The potential energy surface of 4.3 i was explored in search of stationary points possessing either agostic or sigma interactions between the propanedithiolate bridge and vacant apical coordination site. These calculations led to location of a stationary point corresponding to a $\beta$-hydride activation product, 4.3 g , possessing calculated $\mathrm{Fe}-\mathrm{H}, \mathrm{Fe}-\mathrm{C}$, and C-H bond lengths of $1.50,2.03$, and $2.40 \AA \AA$ respectively, and an additional species exhibiting a $\beta$-hydrogen sigma interaction, 4.3h. The $\beta$ hydride activation product is calculated to be $3.2 \mathrm{kcal} \mathrm{mol}^{-1}$ lower in energy relative to the apical carbonyl loss, 4.3 i , and is the only of the nine isomers calculated to have a vCO mode higher in energy relative to the highest energy vCO band of the parent hexacarbonyl complex.

To identify the relationships between the calculated stationary points, the energies associated with their interconversion, and ultimately which isomers are formed following matrix photolysis, transition states on the potential energy surface were located. With regard to the mechanism of formation of the $\beta$-hydride activation
species, the barrier for formation of the $\beta$-hydrogen sigma complex, 4.3h, was found to lay just $0.3 \mathrm{kcal} \mathrm{mol}^{-1}$ higher in energy than the apical carbonyl loss isomer, 4.3i, while the barrier associated with activation of the $\mathrm{C}-\mathrm{H}$ bond to give the $\beta$-hydride complex, 4.3 g , is placed $2.8 \mathrm{kcal} \mathrm{mol}^{-1}$ above the 4.3 h . These low-energy transition states suggest that facile $\beta$-hydride activation may occur following apical photodecarbonylation while the molecule is still vibrationally hot, giving rise to the species possessing the high-energy vCO mode observed in our matrix photolysis experiments. Rotation of the iron tricarbonyl moiety of the $\beta$-hydride activation product results in formation of the bridging carbonyl $\beta$-hydrogen sigma complex, 4.3 c , with a barrier of $5.8 \mathrm{kcal} \mathrm{mol}^{-1}$. The results of these calculations are summarized in Scheme 4.4.

Scheme 4.4: TZP/TPSS-D3(BJ) DFT reaction energies ( $\mathrm{kcal} \mathrm{mol}^{-1}$ ) for pathway of C-H activation of the propanedithiol bridge of $(\mu-\mathrm{pdt})\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}$.

Two additional mechanisms were found that may result in formation of the various bridging carbonyl stationary points. In the first, simple rotation of the $\mathrm{Fe}(\mathrm{CO})_{3}$ moiety of the apical carbonyl loss species 4.3i leads to the bridging carbonyl species 4.3 f with a barrier of $1.4 \mathrm{kcal} \mathrm{mol}^{-1}$. The $\beta$-hydrogen agostic species, 4.3 b , may then be formed from $4.3 f$ with a barrier of just $0.3 \mathrm{kcal} \mathrm{mol}^{-1}$, Scheme 4.5 (solid trace). In the second mechanism, the 4.3 h isomer is formed by the same mechanism in Scheme 4.4. Rotation of the $\mathrm{Fe}(\mathrm{CO})_{3}$ moiety may then lead to 4.3 b with a barrier of $1.4 \mathrm{kcal} \mathrm{mol}^{-1}$, Scheme 4.5 (dashed trace). The barrier associated with the interconversion between $\beta$-hydrogen agostic species, 4.3b, and the $\beta$-hydrogen sigma complex, 4.3 c , is placed $1.3 \mathrm{kcal} \mathrm{mol}^{-1}$ above 4.3 b .

Scheme 4.5: TZP/TPSS-D3(BJ) DFT reaction pathway and energies $\left(\mathrm{kcal} \mathrm{mol}^{-1}\right)$ for formation of bridging carbonyl isomers.

Based on the results of DFT computations, we assign the carbonyl loss product exhibiting vCO modes at 2052, 1998, 1973, and $1942 \mathrm{~cm}^{-1}$ following $\lambda_{\mathrm{irr}}=$ $450 \pm 70 \mathrm{~nm}$ photolysis to the basal loss isomer, 4.3 e , consistent with the results of ultrafast solution experiments. The additional species that grows in following photolysis at these wavelengths, possessing vCO absorptions at 2081, 1982, and $1961 \mathrm{~cm}^{-1}$, is assigned to the $\beta$-hydride activation product, 4.3 g . This assignment is based largely upon the $2081 \mathrm{~cm}^{-1}$ absorption that is shifted to higher energy relative to the parent hexacarbonyl complex, consistent with oxidative addition occurring at a vacant apical coordination site. We propose that the small barrier associated with the activation of this $\mathrm{C}-\mathrm{H}$ bond is responsible for the absence of any spectral features assignable to the apical CO loss isomer, 4.3i, and that formation of the 4.3 i isomer leads directly to formation of the metastable $\beta$-hydride activation product under steady-state photolysis conditions. While the formal oxidative addition reaction we propose is unique to our study, the activation of a $\beta$-hydrogen is not entirely unprecedented in this family of compounds. Previous work by Seyferth and coworkers found that reaction of alkyldithiolate bridged diiron hexacarbonyl tetrahedrane complexes with lithium diisopropyl amide (LDA) leads to abstraction of a $\beta$-hydrogen and in some cases a $\beta$-elimination product. ${ }^{[36]}$ More recently, Zheng et al. found that oxidation of an [FeFe]-hydrogenase model complex possessing a pendant amine diphosphine ligand resulted in heterolysis of a $\beta-\mathrm{CH}$ bond and formation formation of an $\mathrm{Fe}-\mathrm{C}$ bond and protonation of the pendant amine ligand. ${ }^{[37]}$

Finally, the species that is characterized by vCO absorptions at 2025, 2012, and $1843 \mathrm{~cm}^{-1}$ that is produced following $\lambda_{\mathrm{irr}}=330 \pm 70 \mathrm{~nm}$ photolysis is assigned to the bridging carbonyl $\beta$-hydrogen agostic structure 4.3b. This is a somewhat arbitrary assignment; the DFT calculated infrared spectra of bridging carbonyl isomers 4.3b and 4.3c are effectively identical, giving no way to distinguish between the two isomers by FTIR, and both are calculated to be nearly degenerate in energy. The relatively small calculated barrier for interconversion between the two forms of $1.3 \mathrm{kcal} \mathrm{mol}^{-1}$ implies that both forms may very well be present but simply fail to resolve in the matrix FTIR spectra. The exact mechanism for the formation of the bridging carbonyl species also remains unclear. This isomer is present as a minor product following $\lambda_{\text {irr }}=450 \pm 70 \mathrm{~nm}$ irradiation, but as a major product following photolysis at wavelengths < 380 nm . These results suggest a CO loss isomer must possess appreciable vibrational energy following decarbonylation to overcome the reaction barrier associated with the formation of the bridging isomer, in the current case, this would be consistent with the mechanism presented in Scheme 4.4. The two mechanisms proposed in Scheme 4.5, while lower in energy, would be expected to result in formation of a bridging carbonyl isomer in similar population to the $\beta$ hydride activation product following $\lambda_{\text {irr }}=450 \pm 70 \mathrm{~nm}$ due to the similar reaction barriers, which is not observed. Additionally, the apparent photoequilibrium that is established following $\lambda_{\text {irr }}<380 \mathrm{~nm}$ suggests interconversion between the bridging carbonyl and $\beta$-hydride activation isomers, which is also consistent with the mechanism in Scheme 4.4. The overall photochemistry is summarized in Scheme 4.6.

Scheme 4.6: Proposed photochemical behavior and product vibrational modes $\left(\mathrm{cm}^{-1}\right)$ of $(\mu-\mathrm{pdt})\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}$ in hydrocarbon matrices at 85 K .

## Photolysis of ( $\mu$-edt)[ $\left.\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}$ at 85 K in Hydrocarbon Matrices

We next examined the photochemistry of the $\left(\mu\right.$-edt) $\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}$ (edt $=1,2-$ ethaneditholate) model complex, 4.1c. While ( $\mu$-edt) $\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}$ has $\beta$-hydrogens capable of undergoing addition to a vacant metal coordination site as observed with the pdt model complex, the reduced flexibility of the shorter ethanedithiol bridge would be expected to increase the barrier of this reaction. We reasoned this higherenergy barrier may allow for an intermediate prior to $\beta$-hydride activation, e.g. the apical carbonyl loss species, to be observed. Photolysis of $(\mu$-edt $)\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}$ in a Nujol matrix at 85 K with $\lambda_{\text {irr }}=330 \pm 70 \mathrm{~nm}$ results in bleaching of the parent CO bands at 2078, 2037, 2006, and $1992 \mathrm{~cm}^{-1}$ with concomitant appearance of "free" CO (2132 $\mathrm{cm}^{-1}$ ) and product bands at 2084, 2065, 2053, 2025, 2019, 1999, 1977, 1963, 1946, and $1849 \mathrm{~cm}^{-1}$, Figure 4.4.

Figure 4.4. Photolysis of $(\mu$-edt $)\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}$ in glassy Nujol at 85 K. 15 minute $330 \pm$ 70 nm irradiated sample minus unphotolyzed sample.

By way of analogy to the $(\mu-\mathrm{pdt})\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}$ photolysis, we assign the product bands at 2053, 1999, 1977, and $1946 \mathrm{~cm}^{-1}$ to a basal carbonyl loss structure, Scheme 4.7a. Similarly, the species with a vCO band shifted to higher energy relative to the parent complex at $2084 \mathrm{~cm}^{-1}$ is assigned to the $\beta$-hydride activation product, 4.7 e . The weak product absorptions at 2025, 2019, and $1849 \mathrm{~cm}^{-1}$ are assigned to a minor population of the bridging carbonyl isomer, 4.7c. Finally, the remaining product vCO absorption at $2065 \mathrm{~cm}^{-1}$, which has no direct analogue in the photochemistry of $(\mu-\mathrm{pdt})\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}$, is assigned to the apical carbonyl loss isomer,
4.7b. DFT computations predict the high energy vCO transition of the apical carbonyl loss isomer to be approximately $12 \mathrm{~cm}^{-1}$ higher in energy relative the basal carbonyl loss isomer, in excellent agreement with the experimentally observed value. The absence of other spectral features attributable to the apical carbonyl loss product is credited to the low population of this species and significant spectral overlap with 4.7a, resulting in additional vCO vibrational modes failing to resolve.

$\Delta \mathrm{G} \stackrel{\mathrm{a}}{=} 0.0$

$\Delta G \stackrel{b}{=} 3.2$

$\Delta G \stackrel{C}{=} 6.3$

Scheme 4.7. TZP/TPSS-D3(BJ) DFT energies ( $\mathrm{kcal} \mathrm{mol}^{-1}$ ) of the five lowest energy isomers of $(\mu$-edt $)\left[\mathrm{Fe}_{2}(\mathrm{CO})_{5}\right]$.

As was found for the isomers of $(\mu-\mathrm{pdt}) \mathrm{Fe}_{2}(\mathrm{CO})_{5}$, the only isomer of $(\mu-$ edt) $\mathrm{Fe}_{2}(\mathrm{CO})_{5}$ that is calculated to have a vCO vibrational mode shifted to higher energy relative to any of those of the parent hexacarbonyl complex is the $\beta$-hydride activation product, 4.7e. DFT calculated energies for isomers of $\left(\mu\right.$-edt) $\mathrm{Fe}_{2}(\mathrm{CO})_{5}$ show, that as expected, 4.7 e is significantly higher in energy, $9.6 \mathrm{kcal} \mathrm{mol}^{-1}$, relative to the apical carbonyl loss isomer. The barrier associated with $\beta \mathrm{C}-\mathrm{H}$ activation and
the conversion of 4.7 b to 4.7 e is also much higher than the analogous process for $(\mu-\mathrm{pdt}) \mathrm{Fe}_{2}(\mathrm{CO})_{5}$, calculated to be $17.0 \mathrm{kcal} \mathrm{mol}^{-1}$, Scheme 4.8. This high energetic expense for $\beta$-hydride activation in ( $\mu$-edt) $\mathrm{Fe}_{2}(\mathrm{CO})_{5}$ is consistent with the minor population of 4.6 e observed in these experiments compared to the matrix photochemistry ( $\mu-\mathrm{pdt}) \mathrm{Fe}_{2}(\mathrm{CO})_{5}$.

Scheme 4.8: TZP/TPSS-D3(BJ) DFT reaction pathway and energies ( $\mathrm{kcal} \mathrm{mol}^{-1}$ ) for interconversion of isomers of $(\mu$-edt $)\left[\mathrm{Fe}_{2}(\mathrm{CO})_{5}\right]$.

The major product, assigned to the basal carbonyl loss isomer, has similar band positions to those of the ( $\mu-\mathrm{pdt}) \mathrm{Fe}_{2}(\mathrm{CO})_{5}$ basal carbonyl loss species, and is
calculated to be the lowest energy isomer of ( $\mu$-edt) $\mathrm{Fe}_{2}(\mathrm{CO})_{5}$. Interestingly, the barrier for rotation of the $\mathrm{Fe}(\mathrm{CO})_{3}$ moiety of 4.7 b , a process that would yield the bridging carbonyl product 4.7 c , is calculated to be $7.5 \mathrm{kcal} \mathrm{mol}^{-1}$ (Scheme 4.8 , solid trace), much higher than that calculated for a similar process in ( $\mu$-pdt) $\mathrm{Fe}_{2}(\mathrm{CO})_{5}$ (Scheme 4.5, solid trace). This increase in barrier energy, and decrease in barrier for the reverse process to $4.4 \mathrm{kcal} \mathrm{mol}^{-1}$, may be responsible for the low abundance of the bridging carbonyl isomer in these matrix experiments and may also contribute to the observable population of the apical carbonyl loss isomer. Alternatively, formation of the bridging carbonyl isomer may be predicated upon the formation of the $\beta$-hydride activation product as was suggested in the photochemistry of the pdt bridged model complex. In this case, only a minor population of the $\beta$-hydride activated product is generated and available to undergo secondary rearrangement, resulting in the trace population of the bridging carbonyl isomer in the low-temperature matrix photolysis. The vibrational modes and structures of the observed photoproducts are summarized in Scheme 4.9.

Scheme 4.9: Observed product vibrational modes $\left(\mathrm{cm}^{-1}\right)$ in the photochemistry of $(\mu$-edt $)\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}$ in hydrocarbon matrices at 85 K .

## Photolysis of $(\mu$-mdt $)\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}$ at 85 K in Hydrocarbon Matrices

To further explore the influence of the length and flexibility of the alkyl dithiolate bridge upon the photochemistry of [FeFe]-hydrogenase model complexes, we next studied the $(\mu-\mathrm{mdt})\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}(\mathrm{mdt}=$ methanedithiolate $)$ model complex, 1 d . Despite the methanedithiolate bridge being more geometrically constrained than either of the pdt or edt alkyl dithiolate bridges, we anticipated facile formation of a $\mathrm{C}-\mathrm{H}$ activated product due to the positioning of the $\mathrm{CH}_{2}$ bridgehead near an iron apical coordination site. We reasoned that $\beta$-hydride activation would occur following a molecular vibration of the methaneditholate bridge within the $\mathrm{Fe}-\mathrm{Fe} \mathrm{C}_{\mathrm{s}}$ plane subsequent to apical carbonyl photoejection, leading to a low-strain $\mathrm{C}-\mathrm{H}$ activation product.

Photolysis of $(\mu-\mathrm{mdt})\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}$ in a Nujol matrix at 85 K with $\lambda_{\text {irr }}=330 \pm 70 \mathrm{~nm}$ results in bleaching of the parent vCO bands with concomitant appearance of "free" CO (2132 cm ${ }^{-1}$ ) and product bands at 2083, 2068, 2055, 2027, 2013, 2001, 1978, 1947, and $1849 \mathrm{~cm}^{-1}$, Figure 4.5. As anticipated, the high-energy vCO absorption characteristic of the $\beta$-hydride activation product is much more intense relative to the other photoproduct $v C O$ bands when compared to the results of the ( $\mu$ edt) $\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}$ matrix photochemistry experiment, suggesting more facile activation of a mdt C-H bond.

Figure 4.5: Photolysis of $(\mu-\mathrm{mdt})\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}$ in glassy Nujol at 85 K .15 minute $330 \pm$ 70 nm irradiated sample minus unphotolyzed sample.

DFT computations on the isomers of $(\mu-\mathrm{mdt}) \mathrm{Fe}_{2}(\mathrm{CO})_{5}$ reveal six stationary points, Scheme 4.10. The lowest energy geometry is again found to be the basal carbonyl loss isomer, 4.10a, with the apical carbonyl loss isomer, 4.10b, calculated to be just $1.0 \mathrm{kcal} \mathrm{mol}{ }^{-1}$ higher in energy. Two isomers were found that possess a bridging carbonyl group, 4.10 c , placed $1.8 \mathrm{kcal} \mathrm{mol}^{-1}$ above 4.10 a , and 4.10 e which has also undergone $\beta$-hydride activation of the mdt bridge placed $8.6 \mathrm{kcal} \mathrm{mol}^{-1}$ higher in energy than 4.10a. 4.10e is a unique geometry in the current study, among
all of the alkyl dithiolate bridges studied, the mdt bridged complex is the only one found to have a stationary corresponding to a $\beta$-hydride activated bridging carbonyl complex. The remaining stationary points are the $\beta$-hydride activation product 4.10d, and the closely related $\beta$-hydride sigma complex, 4.10 f . As was found in the previous experiments, the $\beta$-hydride activation isomer, 4.10 d , is the only isomer calculated to have a vCO absorption shifted to higher energy relative to the parent hexacarbonyl complex.

Scheme 4.10. TZP/TPSS-D3(BJ) DFT energies (kcal mol ${ }^{-1}$ ) of the six lowest energy isomers of $(\mu$-mdt $)\left[\mathrm{Fe}_{2}(\mathrm{CO})_{5}\right]$.

Reaction Coordinate
Scheme 4.11. TZP/TPSS-D3(BJ) DFT reaction pathway and energies (kcal mol ${ }^{-1}$ ) for formation for $\mathrm{C}-\mathrm{H}$ activated and bridging carbonyl isomers of $(\mu-\mathrm{mdt})\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}$.

Exploring the potential energy surface of the apical carbonyl loss isomer of $(\mu-\mathrm{mdt}) \mathrm{Fe}_{2}(\mathrm{CO})_{5}$, Scheme 4.11, reveals that the barrier for $\beta$-hydride activation of the mdt bridge to give isomer 4.10 d is $4.11 .1 \mathrm{kcal} \mathrm{mol}^{-1}$, and is preceded by the formation of the $\beta$-hydride sigma complex 4.10f. This is significantly lower in energy than the analogous process for the edt bridged complex, placed at $17.0 \mathrm{kcal} \mathrm{mol}^{-1}$, but still much higher than the $2.6 \mathrm{kcal} \mathrm{mol}^{-1}$ calculated for the pdt bridged model complex. The intermediate energy required for mdt $\beta$-hydride activation can be rationalized as being due to increased strain relative to the highly flexible pdt alkyl dithiolate bridged complex, but having lower strain relative to the edt bridged due to the position of the mdt C-H bond near the apical iron coordination site within the $\mathrm{C}_{\mathrm{s}}$ plane of the molecule.

Two mechanisms were found that may result in the formation of the bridging carbonyl isomer 4.10c. In the first, simple rotation of the $\mathrm{Fe}(\mathrm{CO})_{3}$ moiety of 4.10 b may result in formation of the bridging carbonyl species 4.10 c with a barrier of 6.9 kcal $\mathrm{mol}^{-1}$. Alternatively, rotation of the $\mathrm{Fe}(\mathrm{CO})_{3}$ moiety of the $\beta$-hydride activation product, 4.10 d , may result in the formation of isomer 4.9 e , which may then undergo C-H elimination of the mdt bridge to give isomer 4.10 c with a barrier of $7.6 \mathrm{kcal} \mathrm{mol}^{-}$ ${ }^{1}$, Scheme 4.11 (dashed trace). It is unclear whether formation of the bridging carbonyl isomer in the low-temperature matrix photochemistry experiments proceeds exclusively through either of these mechanisms. The calculated barrier for rotation of the $\mathrm{Fe}(\mathrm{CO})_{3}$ moiety of the apical carbonyl loss isomers of both the mdt and edt model complexes are very similar in energy, however, the bridging carbonyl isomer of $(\mu-\mathrm{edt}) \mathrm{Fe}_{2}(\mathrm{CO})_{5}$ is only present as a trace photoproduct, whereas the bridging carbonyl isomer represents a major photoproduct in the photochemistry of $(\mu-\mathrm{mdt}) \mathrm{Fe}_{2}(\mathrm{CO})_{6}$. This may be due to the bridging carbonyl loss isomer of $(\mu-$ $\mathrm{mdt}) \mathrm{Fe}_{2}(\mathrm{CO})_{5}$ being disfavored by just $0.8 \mathrm{kcal} \mathrm{mol}^{-1}$ relative to the apical carbonyl loss isomer versus $3.1 \mathrm{kcal} \mathrm{mol}^{-1}$ for the isomers of $\left(\mu\right.$-edt) $\mathrm{Fe}_{2}(\mathrm{CO})_{5}$, leading to a greater population of the bridging isomer in the photoequilibrium of the mdt model complex. Alternatively, the results from the photochemistry of $(\mu-\mathrm{pdt}) \mathrm{Fe}_{2}(\mathrm{CO})_{5}$ seem to suggest that the formation of the bridging carbonyl isomer is preceded by $\beta$ hydride activation of the alkyldithiolate bridge. In the present case, the greater population of the bridging carbonyl isomer in the photochemistry of $(\mu-\mathrm{mdt}) \mathrm{Fe}_{2}(\mathrm{CO})_{6}$ relative to that of $(\mu$-edt $) \mathrm{Fe}_{2}(\mathrm{CO})_{6}$ could then be attributed to the more facile $\mathrm{C}-\mathrm{H}$ bond activation of the methanedithiolate bridge relative to the 1,2-ethanedithiolate.

Using the results of DFT computations and the results of the above matrix photolysis experiments, we assign the species giving rise to the 2055, 2001, 1978, and 1947 $\mathrm{cm}^{-1}$ vibrational modes to the basal carbonyl loss isomer, 4.10a, and the $1968 \mathrm{~cm}^{-1}$ vibrational mode to a minor population of the apical carbonyl loss isomer, 4.10b. The bridging carbonyl isomer, 4.10c, is assigned to the 2027 , 2013, and $1849 \mathrm{~cm}^{-1}$ absorptions. The remaining band at $2083 \mathrm{~cm}^{-1}$, shifted to higher energy relative to the parent hexacarbonyl complex, is again assigned to the $\beta$-hydride activation product, 4.10d. The vibrational modes and structures of the observed photoproducts are summarized in Scheme 4.12.

Scheme 4.12: Observed product vibrational modes $\left(\mathrm{cm}^{-1}\right)$ in the photochemistry of $(\mu$-mdt $)\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}$ in hydrocarbon matrices at 85 K .

## Photolysis of ( $\mu$-bdt) $\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}$ at 85 K in Hydrocarbon Matrices

Finally, we turned our attention towards the dithiolene bridged model complex ( $\mu$-bdt) $\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}(\mathrm{bdt}=1,2$-benzenedithiolate), Scheme 4.1e. The absence of any CH bonds on the dithiolene $\beta$-carbons eliminates the possibility of $\beta$-hydride activation, making this an attractive target for confirmation of the assignments made in the photochemistry of the alkyl dithiolate bridged complexes. The $\left(\mu\right.$-bdt) $\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}$
parent molecule exhibits five well-defined carbonyl stretching modes at 2079, 2044, 2004, 1969, and $1957 \mathrm{~cm}^{-1}$ in Nujol at 85 K.

Photolysis of $(\mu-\mathrm{bdt})\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}$ with $\lambda_{\text {irr }}=400 \pm 70 \mathrm{~nm}$ results in bleaching of the parent carbonyl vibrational modes and concomitant growth of a band at 2132 $\mathrm{cm}^{-1}$, corresponding to matrix trapped CO, and appearance of product bands at 2065, 2056, 2009, 1995, 1987, 1980, 1953, and $1943 \mathrm{~cm}^{-1}$, Figure 4.6a. Photolysis at higher energy, $\lambda_{\text {irr }}=330 \pm 70 \mathrm{~nm}$, results in the growth of bands at 2026, $2017 \mathrm{~cm}^{-1}$, and a feature in the bridging carbonyl region at $1861 \mathrm{~cm}^{-1}$, Figure 4.6b. Photolysis at these wavelengths also leads to reduction in the intensity of the 2065 and $1943 \mathrm{~cm}^{-}$ ${ }^{1}$ absorptions relative to the 2056 and $1953 \mathrm{~cm}^{-1}$ photoproduct vCO vibrational modes. Warming of the hydrocarbon glass to 135 K results in recapture of liberated CO and reversion to the parent hexacarbonyl complex. Notably absent in these spectra are any product bands higher in energy relative to the parent hexacarbonyl complex that would be consistent with formal oxidation of a carbonyl loss photoproduct, supporting the assignment of $\beta$-hydride activation in the photochemistry of the alkyl dithiolate bridged model complexes.

Figure 4.6. Photolysis of $(\mu$-bdt $)\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}$ in glassy Nujol at 85 K. (a) 60 minute 400 $\pm 70 \mathrm{~nm}$ irradiated sample minus unphotolyzed sample. (b) 45 minute $330 \pm 70 \mathrm{~nm}$ irradiated sample minus $400 \pm 70 \mathrm{~nm}$ irradiated sample.

The products formed following $\lambda_{\text {irr }}=400 \pm 70 \mathrm{~nm}$ photolysis are consistent with formation of two different CO loss products possessing solely terminal carbonyls, assigned to basal and apical CO loss isomers. With higher energy photolysis, $\lambda_{\text {irr }}=330 \pm 70 \mathrm{~nm}$, an isomer possessing a bridging carbonyl grows in exhibiting vCO modes at 2026, 2017, and $1861 \mathrm{~cm}^{-1}$ as well as a reduction in the
relative population of the species responsible for the 2065 and $1943 \mathrm{~cm}^{-1}$, suggesting that this species converts to the bridging carbonyl isomer at these wavelengths.

To understand the nature of the decarbonylation photoproducts of $\left(\mu\right.$-bdt) $\mathrm{Fe}_{2}(\mathrm{CO})_{6}$, DFT computations were conducted on isomers of $(\mu$-bdt) $) \mathrm{Fe}_{2}(\mathrm{CO})_{5}$. These computations resulted in the location of just four low-energy, singlet-state stationary points, Scheme 4.13. Interestingly, the lowest energy isomer is found to be a geometry possessing a bridging carbonyl and an $\mathrm{FeS}_{2} \mathrm{C}_{2}$ metallacycle coordinating the remaining Fe through an $\eta^{5}$ coordination mode, Scheme 4.13a. Isomers possessing vacant basal, 4.13b, and apical, 4.13c, coordination sites are located 5.2 and $7.1 \mathrm{kcal} \mathrm{mol}^{-1}$ higher in energy than 4.13a, respectively. The final stationary point, 13d, features an $\eta^{5}-\mathrm{FeS}_{2} \mathrm{C}_{2}$ metallacycle similar to 4.13 a , but possesses solely terminal carbonyl groups, located $10.4 \mathrm{kcal} \mathrm{mol}^{-1}$ above isomer 4.13a. All but the basal CO loss isomer, 13b, were found to possess an element of $\mathrm{C}_{\mathrm{s}}$ symmetry. No stationary points corresponding to a bridging carbonyl structure without an $\eta^{5}$ $\mathrm{FeS}_{2} \mathrm{C}_{2}$ were located. A $\mathrm{C}_{2 v}$ bridging carbonyl structure in which the benzenedithiolate bridge is perpendicular to the $\mathrm{Fe}-\mathrm{Fe}$ bond corresponds to a transition state for a "flopping" of $\eta^{5}$ coordination of the $\mathrm{FeS}_{2} \mathrm{C}_{2}$ group between the two irons with a barrier of $9.0 \mathrm{kcal} \mathrm{mol}^{-1}$.

$\Delta G=5.2$

$\Delta \mathrm{G}=7.1$

Scheme 4.13: TZP/TPSS-D3(BJ) DFT energies (kcal mol${ }^{-1}$ ) of the four lowest energy isomers of $(\mu-\mathrm{bdt}) \mathrm{Fe}_{2}(\mathrm{CO})_{5}$.

Perhaps the most interesting result of these computations is the electronic structure of the two isomers possessing an $\eta^{5}-\mathrm{FeS}_{2} \mathrm{C}_{2}$ heterometallacycle. For structure 4.13a, the $\mathrm{Fe}-\mathrm{Fe}, \mathrm{S}-\mathrm{Fe}$, and $\mathrm{C}-\mathrm{Fe}$ bond lengths of the $\eta^{5}-\mathrm{FeS}_{2} \mathrm{C}_{2}$ to the coordinated iron were found to be $2.53,2.38$, and $2.25 \AA$, respectively, while 4.13 d had similar bond lengths of $2.54,2.31$, and $2.24 \AA \AA$. Nucleus-independent chemical shift (NICS) calculations taken $1 \AA$ above the plane of the ring structures results in values of -10.6 and -9.1 for the $\mathrm{FeS}_{2} \mathrm{C}_{2}$ and $\mathrm{C}_{6} \mathrm{H}_{4}$ rings, respectively for isomer 4.13a, and -13.6 and -9.6 for isomer 4.13d, consistent with these being aromatic metallacycles. ${ }^{[38,39]}$ Additionally, examining the molecular orbitals of these isomers reveals a high degree of delocalization and nodal surfaces that are suggestive of the $\mathrm{FeS}_{2} \mathrm{C}_{6} \mathrm{H}_{4}$ ring structure behaving as a 10 r-electron aromatic system, Figure 4.7. The recognition of aromatic metallacycle stationary points, while unexpected, is not
necessarily surprising given the diverse chemistry of aromatic dithiolene complexes, ${ }^{[40-43]}$ this is, however a rare example of an aromatic dithiolene metallacycle coordinating another metal through its $\pi$ structure.

Figure 4.7: Molecular orbitals corresponding to nodal surfaces of delocalized $\mathrm{C}_{6} \mathrm{H}_{4} \mathrm{~S}_{2} \mathrm{Fe}$ ring structure.

The potential energy surface of $(\mu$-bdt $) \mathrm{Fe}_{2}(\mathrm{CO})_{5}$ was surveyed to determine the energies associated with the formation of each of the four carbonyl loss isomers and how they may relate to one another, Scheme 4.14. A relatively small barrier of $3.9 \mathrm{kcal} \mathrm{mol}^{-1}$ associated with the collapse of the dithiolene bridge to an $\eta^{5}$ coordination mode to yield 4.13d from 4.13 c was found. Rotation of the $\mathrm{Fe}(\mathrm{CO})_{3}$ group of 13d is predicted to be effectively barrierless, resulting in formation of a bridging carbonyl and the $(\mu-\mathrm{bdt}) \mathrm{Fe}_{2}(\mathrm{CO})_{5}$ global minima structure, 4.13a. This suggests that the 4.13d isomer is not a species present in the matrix photolysis, but is an intermediate in the formation of the bridging carbonyl species.

Scheme 4.14: TZP/TPSS-D3(BJ) reaction pathway for formation of bridging carbonyl species following photodecarbonylation of $\left(\mu\right.$-bdt) $\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}$.

Based on the results of DFT and variable wavelength matrix photochemistry experiments, we propose that irradiation of $(\mu-\mathrm{bdt})\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}$ with $\lambda_{\text {irr }}=400 \pm 70 \mathrm{~nm}$ results in both an apical carbonyl loss isomer (2065, 2009, 1987, $1943 \mathrm{~cm}^{-1}$ ) and a basal carbonyl loss isomer (2056, 1980, $1953 \mathrm{~cm}^{-1}$ ), Scheme 4.15. Photolysis at higher energies, $\lambda_{\mathrm{irr}}=330 \pm 70 \mathrm{~nm}$, results in formation of these same isomers, however, a greater portion of the apical carbonyl loss isomer may retain the vibrational energy necessary to overcome the barrier associated with formation of the $\eta^{5}-\mathrm{FeS}_{2} \mathrm{C}_{2}$ structure, 4.13 d , which then proceeds to form the bridging structure 4.13a (2026, 2017, $1861 \mathrm{~cm}^{-1}$ ).

Scheme 4.15: Observed photochemical behaviour and product vibrational modes $\left(\mathrm{cm}^{-1}\right)$ of $\left(\mu\right.$-bdt) $\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}$ in hydrocarbon matrices at 85 K .

## Conclusions

Photolysis of [FeFe]-hydrogenase model complexes in low-temperature matrices provides a much broader range of products than those observed in ultrafast solution studies. This is largely due to the ability of metastable photogenerated species to be maintained indefinitely at cryogenic temperatures and undergo multiphoton reactions, reaching an eventual photoequilibrium. For [FeFe]-hydrogenase model complexes possessing $\beta$-hydrogens on the dithiolate bridge, results from these low-temperature photolyses and DFT studies demonstrate that C-H bond activation of the dithiolate bridge occurs and results in reversible formation of a $\beta$ hydride activation product. Additionally, formation of photoproducts possessing bridging carbonyls, as found in the enzyme active site, are observed and appear to be preceded by $\beta$-hydride activation.

In the photolysis of $\left(\mu\right.$-bdt) $\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}$, which lacks any $\beta$-hydrogens that may undergo activation and has an element of unsaturation in the dithiol bridge, formation of a $10 \pi$ aromatic metallacycle is observed in addition to the initial apical and basal carbonyl loss products. This aromatic photoproduct appears to be a rare instance in which a dithiolene based aromatic metallacycle is able to coordinate another metal through the $\pi$ structure resulting in an $\eta^{5}$ coordination mode.

## Experimental

All complexes were prepared by reported procedures. ${ }^{[16,36,44-46]}$ The apparatus and methods for matrix photochemistry have been reported elsewhere. ${ }^{[47]}$ All DFT calculations were performed in the Amsterdam Density Functional (ADF2014.02)
program. ${ }^{[48-50]}$ Electronic configurations of atoms were described by an all-electron triple- $\zeta$ Slater-type orbital basis set modified by a polarization function (TZP STO). ${ }^{[51]}$ Geometry optimizations and vibrational frequency calculations were performed using the GGA functional of Becke ${ }^{[52]}$ and Perdew ${ }^{[53,54]}$ as well as the dispersion corrected meta-GGA TPSS-D3(BJ). ${ }^{[55-57]}$ The intrinsic reaction coordinate (IRC) of all calculated transition state geometries was followed to confirm the relation to the expected stationary points. Electronic excitation energies were computed using the statistical average of orbital potentials (SAOP) model, ${ }^{[32,33]}$ with cyclohexane solvent interactions modelled using the COSMO model. ${ }^{[58-60]}$

#### Abstract

Low energy photolysis of $\operatorname{TpM}(\mathrm{CO})_{2}\left(\eta^{3}-\mathrm{C}_{3} H_{4} R\right)$, where Tp=tris(pyrazolyl)borate, $M=$ Mo or $W$, and $R=2-H$ or $2-M e$ in PVC matrices at 85 K results in exo/gauche isomerism of the allyl ligand. This transformation comes in contrast to the behaviour observed in cyclopentadienyl analogues which undergo exolendo isomerism. DFT computations reveal an $\eta^{3} \rightarrow \eta^{1^{*}} \rightarrow \eta^{3}$ mechanism for the allyl rotameric interconversion where the $\eta^{1 *}$-allyl intermediate is generated upon MLCT excitation.

## Introduction

Rotameric fluxionality of the allyl ligand in transition metal complexes is a long recognized process for this class of compounds. ${ }^{1-4}$ The interconversion between endo and exo forms of the allyl rotamers is known to occur both thermally and photochemically. ${ }^{5,6}$ Experimental evidence for two mechanisms of the thermal isomerism have been reported, one occurring through rotation along the metal-allyl axis with retention of the $\eta^{3}$ bonding mode, ${ }^{4,7}$ as well as through an $\eta^{1}$-allyl intermediate. ${ }^{5,8}$ A theoretical study suggests that the degree of antibonding
character between the metal and ancillary ligands in the $\eta^{3}$ rotational transition state dictates which of the two isomerism mechanisms is favored; rotation along the metal-allyl axis being preferred when only a small degree of antibonding character is present in the transition state, and the $\eta^{3} \rightarrow \eta^{1} \rightarrow \eta^{3}$ mechanism being preferred when a high degree of metal-ligand antibonding is present in the $\eta^{3}$ rotational transition state. ${ }^{9}$

In 1967, Trofimenko reported the synthesis of $\operatorname{TpM}(\mathrm{CO})_{2}\left(\eta^{3}-\mathrm{C}_{3} \mathrm{H}_{4} \mathrm{R}\right)(\mathrm{Tp}=$ trispyrazolylborate, $M=M o, W$ and $R=H, M e)$, through the reaction of $\operatorname{TpM}(\mathrm{CO})_{3}{ }^{-}$ with the corresponding allyl halide. ${ }^{10}$ In subsequent publications, the solution dynamics of these fluxional molecules were studied through variable temperature NMR and evidence for rotation of the Tp ligand about the B-M axis was found, but nothing was observed to suggest rotation of the allyl ligand. ${ }^{11,12}$ In $\mathrm{CH}_{2} \mathrm{Cl}_{2}$ solution, these compounds exhibit only two vibrational modes in the metal carbonyl stretching region. The simplicity of this spectrum suggests the presence of a single allyl rotamer in solution. More than two carbonyl vibrational bands, or significant asymmetry arising from overlapping absorptions, would be expected if multiple isomers were present in solution.

The crystal structure of $\mathrm{TpMo}(\mathrm{CO})_{2}\left(\mathrm{n}^{3}-2\right.$-methylallyl) has been reported previously. ${ }^{13}$ Perhaps unexpectedly due to steric considerations, the allyl ligand is found in the exo rotameric form with the allyl methyl group oriented towards the trispyrazolylborate ligand. This comes in contrast to the analogous cyclopentadienyl compounds that favor the endo rotamer with the allyl methyl group facing away from the cyclopentadienyl ring. ${ }^{4,7,14-16}$ For $\mathrm{TpMo}(\mathrm{CO})_{2}\left(\eta^{3}-\mathrm{C}_{3} \mathrm{H}_{4} \mathrm{Me}\right)$, the Mo-allyl bond
lengths are $2.337(5)$ and $2.364(4) \AA$ for the terminal carbons with the bond to the central allyl carbon slightly shorter at $2.258(4) \AA$.

Previous work from our group has established that wavelength dependent photolysis of isoelectronic $\mathrm{CpM}(\mathrm{CO})_{2}\left(\eta^{3}-\mathrm{C}_{3} \mathrm{H}_{4} R\right)(M=\mathrm{Mo}$ and $R=H, \mathrm{Me})$ results in selective population of either the exo or endo rotameric forms, Scheme 5.2. ${ }^{6}$ As an extension of these studies, we sought to examine the photochemistry of the corresponding Tp compounds to study the influence of the increased steric demands of the trispyrazolylborate ligand on the allyl rotamers.

## Results and Discussion

## PVC Matrix Photochemistry at 85 K

Photolysis of $\mathrm{TpM}(\mathrm{CO})_{2}\left(\eta^{3}-\mathrm{C}_{3} \mathrm{H}_{4} R\right)(M=\mathrm{Mo}, \mathrm{W}$ and $\mathrm{R}=\mathrm{H}, \mathrm{Me})$ with $\lambda_{\text {irr }}=450 \pm 50 \mathrm{~nm}$ results in bleaching of the parent vibrational bands with concomitant growth of two new product bands; no new absorbance assignable to "free" CO is present, Figure 5.1. This photoproduct displays an apparent shift of the antisymmetric CO vibrational mode to lower energy, whereas the symmetric CO stretching mode shifts to higher energy. A simple exo/endo rotameric isomerization would be expected to result in a shift of both vibrational bands to either higher or lower energy dependent upon the donor/acceptor ability of the two rotameric forms due to retention of approximate $\mathrm{C}_{s}$ molecular symmetry. The shift of the antisymmetric CO mode to lower energy and increase in energy of the symmetric CO mode may be attributed
to a more pronounced change in molecular symmetry. In the present case, this may correspond to a photogenerated gauche rotamer that would possess only an element of $C_{1}$ symmetry. Back photolysis of the $\lambda_{\text {irr }}=450 \pm 50 \mathrm{~nm}$ irradiated sample with $\lambda_{\mathrm{irr}}=550 \pm 50 \mathrm{~nm}$ results in reversion to the parent complex. Annealing the $\lambda_{\mathrm{irr}}$ $=450 \pm 50 \mathrm{~nm}$ irradiated sample to ca. 155 K also results in reversion to the parent complex. Prolonged $\lambda_{\text {irr }}=550 \pm 50 \mathrm{~nm}$ photolysis of a sample prepared in the dark exhibits no growth of bands assignable to the exo rotamer, suggesting that a single isomer is present in PVC matrices at these temperatures.

Figure 5.1: Photolysis of $\mathrm{TpMo}(\mathrm{CO})_{2}\left(\eta^{3}-\mathrm{C}_{3} \mathrm{H}_{5}\right)$ in PVC at 85 K . (a) Difference spectrum obtained following $\lambda_{\mathrm{irr}}=450 \pm 50 \mathrm{~nm}$ photolysis of unphotolyzed sample. (b) Difference following $\lambda_{\text {irr }}=550 \pm 50 \mathrm{~nm}$ back photolysis of $\lambda_{\mathrm{irr}}>450 \mathrm{~nm}$ irradiated sample.

## DFT Study

## Potential Energy Surface Along the $\boldsymbol{\eta}^{3}-\mathrm{C}_{3} \mathrm{H}_{5}$ Rotational Axis

To gain a clearer understanding of the observed photochemical behaviour, a DFT investigation was carried out in order to identify stationary points along the $\eta^{3}-\mathrm{C}_{3} \mathrm{H}_{4} R$ rotational axis. For the four complexes studied, each was found to possess local minima featuring the allyl ligand in exo, gauche, and endo rotameric forms, the results of these calculations are summarized in Table 5.1. In all cases, the exo rotamer was found to be the lowest energy conformation followed by gauche and endo. For $\mathrm{TpMo}(\mathrm{CO})_{2}\left(\eta^{3}-\mathrm{C}_{3} \mathrm{H}_{5}\right)$, the transition state between the exo and gauche rotamers was calculated to lay $9.7 \mathrm{kcal} \mathrm{mol}^{-1}$ higher in energy than the exo geometry. The transition state for the gauche to endo transformation was placed at 1.3 kcal $\mathrm{mol}^{-1}$. Interestingly, for all four complexes, the local minima of the endo rotamer is calculated to be exceedingly shallow with the transition state for the endo to gauche rotameric isomerism calculated to be less than ca. $0.2 \mathrm{kcal} \mathrm{mol}^{-1}$, Figure 5.2. The near barrierless endo $\rightarrow$ gauche isomerization suggests that if the endo isomer were produced photochemically in the matrix, it would likely retain sufficient energy to relax to the gauche rotamer even at cryogenic temperatures.

Figure 5.2: Calculated energy surface along the $\eta^{3}-\mathrm{C}_{3} \mathrm{H}_{5}$ rotational mode.

For $\mathrm{M}=\mathrm{Mo}$, DFT calculated vCO frequencies are consistent with the assignment of photochemical generation of the gauche rotamer at 85 K . Relative to the exo rotamer, the symmetric vCO mode of the gauche form is calculated to be higher in energy while the antisymmetric vCO mode lower in energy. For $\mathrm{M}=\mathrm{W}$, both the symmetric and antisymmetric vCO vibrational modes of the gauche rotamers are calculated to be lower in energy relative to those of the exo rotamers, though the symmetric vCO modes are effectively degenerate.

In the gauche orientation, the Mo-allyl bond lengths are calculated at 2.360 and $2.377 \AA$ for the terminal carbons while the bond to the central carbon is placed at $2.313 \AA$. The similar Mo-C bond lengths demonstrate that the allyl ligand is coordinating roughly equally in an $\eta^{3}$ manner between each of the allyl carbons; the change to gauche orientation is not the result of the formation of a 17-electron complex with the allyl group coordinating in an $\eta^{2}$ fashion.

Frontier orbitals for the exo $\leftrightarrow$ gauche $\left(\mathrm{TS}_{1}\right)$ and gauche $\leftrightarrow$ endo $\left(\mathrm{TS}_{2}\right)$ transition states are presented in Figure 5.3. In both cases the HOMO corresponds to orbitals that are dominated by backbonding interactions between metal d and $\mathrm{CO} \pi^{*}$ orbitals. This interaction may lead to a stabilizing effect on the rotational transition states that results in the low computed energy barrier. What remains unclear is why no evidence for rotation of the allyl ligand has been observed in previous NMR experiments or in the current solution study. ${ }^{11,12,17}$ It is possible that the rotational barrier is sufficiently low in energy that the experiments conducted in $\mathrm{CDCl}_{3}$ solvent simply were unable to attain a low enough temperature to observe any broadening or coalescence of the allyl ${ }^{1} \mathrm{H}$ resonances. However, this argument fails to account for the presence of only a single rotamer in the current PVC matrix photolyses.

The energies for an electronic ground state $\eta^{3} \rightarrow \eta^{1} \rightarrow \eta^{3}$ isomerism mechanism were also computed. The barrier for this pathway was calculated to be substantially higher than the $\eta^{3} \rightarrow \eta^{3} \rightarrow \eta^{3}$ rotational mechanism at ca. $32 \mathrm{kcal} \mathrm{mol}^{-1}$ and was not considered further as a ground state rotational mechanism.

Figure 5.3: Frontier orbitals of the exo $\leftrightarrow$ gauche $\left(\mathrm{TS}_{1}\right)$ and gauche $\leftrightarrow e n d o\left(\mathrm{TS}_{2}\right)$ transitions states.

## Electronic Structure of $\mathrm{TpM}(\mathrm{CO})_{2}\left(\boldsymbol{n}^{3}-\mathrm{C}_{3} \mathrm{H}_{4} \mathrm{R}\right)$

The electronic spectra of $\mathrm{TpM}(\mathrm{CO})_{2}\left(\eta^{3}-\mathrm{C}_{3} \mathrm{H}_{4} \mathrm{R}\right)$ are presented in Figure 5.4. For $M=M o$, the primary feature in the region of the spectrum that the observed photochemical transformation occurs is an absorbance with maxima centered at 378
$\mathrm{nm}\left(\varepsilon=1.35\right.$ and $1.38 \times 10^{3} \mathrm{M}^{-1} \mathrm{~cm}^{-1}$ for $\mathrm{R}=\mathrm{H}$, Me respectively) with a tail that extends to ca. 510 nm . For $\mathrm{M}=\mathrm{W}$, this band is slightly blue shifted, centered at 368 $\mathrm{nm}\left(\varepsilon=1.68\right.$ and $1.74 \times 10^{3} \mathrm{M}^{-1} \mathrm{~cm}^{-1}$ for $\mathrm{R}=\mathrm{H}$, Me respectively), with a tail extending to ca. 500 nm . Time-dependent density functional theory (TD-DFT) calculations of electronic excitation energies using the statistical average of model orbital potentials (SAOP) model suggest that this low energy absorption consists of two overlapping electronic transitions, a HOMO $\rightarrow$ LUMO excitation ( 3.260 eV ) and a HOMO$1 \rightarrow$ LUMO excitation ( 3.355 eV ), Figure 5.5. For the exo geometry, the HOMO-1 orbital predominantly corresponds to a bonding interaction between the allyl $\pi^{*}$ antibonding orbital with the metal $\mathrm{d}_{\mathrm{xz}}, \mathrm{d}_{\mathrm{z}}{ }^{2}$, and $\mathrm{d}_{\mathrm{yz}}$ orbitals. The HOMO is dominated by a bonding interaction between the metal $\mathrm{d}_{\mathrm{x}-\mathrm{y}}{ }^{2}$ orbital and $\mathrm{CO} \pi^{*}$ orbitals. Finally, the LUMO is composed primarily of an antibonding interaction between the metal $\mathrm{d}_{\mathrm{xy}}$ orbital with the allyl $\pi$ non-bonding orbital. Excitation from either the HOMO or HOMO-1 into the LUMO would be expected to result in reduction of the bond order between the metal and allyl fragment that may facilitate the rotameric isomerization observed in the low-temperature matrix photolysis experiments.

Figure 5.4: Electronic spectra of $\operatorname{TpM}(\mathrm{CO})_{2}\left(\eta^{3}-\mathrm{C}_{3} \mathrm{H}_{4} R\right)$ compounds studied in $\mathrm{CH}_{2} \mathrm{Cl}_{2}$ solution.

As the observed photoproduct, putatively the gauche rotamer, reverts to exo$\operatorname{TpM}(C O)_{2}\left(\eta^{3}-C_{3} H_{4} R\right)$ upon $\lambda_{\text {irr }}=550 \pm 50$ nm photolysis, it may be assumed that this rotamer has an electronic absorption in this portion of the spectrum. Accordingly, SAOP excitation energies place two transitions lower in energy than those observed for exo-TpM(CO) $\left(\eta^{3}-\mathrm{C}_{3} \mathrm{H}_{4} R\right)$; a HOMO $\rightarrow$ LUMO excitation ( 3.013 eV ) and a HOMO$1 \rightarrow$ LUMO excitation ( 3.230 eV ). For the gauche isomer, the HOMO-1 corresponds to a bonding interaction between the $\mathrm{CO} \pi^{*}$ antibonding orbitals and metal $\mathrm{d}_{\mathrm{x}-\mathrm{y}}{ }^{2}, \mathrm{~d}_{\mathrm{yz}}$, $d_{x z}$, and $d_{z}{ }^{2}$ orbitals. The HOMO is composed of a bonding interaction between the allyl $\pi^{*}$ antibonding orbital with the metal $d_{x z}, d_{x-y}{ }^{2}{ }^{2}$, and $d_{x y}$ orbitals. The LUMO is predominantly ligand based, featuring a bonding interaction between a $\mathrm{CO} \pi^{*}$ orbital
and metal. The reduction of symmetry of the allyl group in the gauche orientation leads to an allene-like $\pi$ bonding orbital that forms a bonding interaction with the metal d orbitals. Occupation of this orbital may be expected to result in localization of the $\pi$ electrons and give rise to a formal C-C double bond in the excited state.

## Excited State Geometries

To further explore how population of the low energy electronic excited states of the exo rotameric form may facilitate rotameric interconversion, excited-state geometry optimizations were performed for the two lowest energy electronic excited states.

1A Excited State

2A Excited State

Figure 5.6: Calculated excited state geometries of $\mathrm{TpMo}(\mathrm{CO})_{2}\left(\mathrm{n}^{3}-\mathrm{C}_{3} \mathrm{H}_{5}\right)$ compounds.

Optimizing for the 1A state of exo-TpM $(\mathrm{CO})_{2}\left(\eta^{3}-\mathrm{C}_{3} \mathrm{H}_{5}\right)$, corresponding to the HOMO $\rightarrow$ LUMO excitation, results in localization of the allyl $\pi$ electrons to give a double bond between a terminal allyl carbon and the central allyl carbon, the remaining terminal carbon is found to be approximately $\mathrm{sp}^{3}$ hybridized with a single bond to the metal center, Figure 5.6. The bond length between the metal and $\mathrm{sp}^{3}$ allyl carbon is placed at $2.29 \AA$, while the distance to the central carbon is $2.57 \AA$. The $\mathrm{sp}^{2}$ terminal carbon shares little bonding character with the metal at a distance of $3.40 \AA$. The $\mathrm{sp}^{3}$ terminal carbon to central carbon bond length is calculated as $1.45 \AA$ while the bond length between the central carbon and $\mathrm{sp}^{2}$ terminal carbon is placed at $1.39 \AA \AA$, consistent with greater double bond character. Worth noting is the
rotation of the allyl group, such that the B-Mo-C-C dihedral is reduced to only $12^{\circ}$, approaching the near $0^{\circ}$ dihedral of the gauche rotamer. Relaxation of this excited state represents a viable route to the gauche rotamer.

The 2A excited state, arising from the HOMO-1 $\rightarrow$ LUMO excitation, which is also calculated to occur in the region of the observed photochemistry, shares much in common with the 1A excited state. Localization of the $\pi$ electrons is found to occur accompanied by approximate $\mathrm{sp}^{3}$ hybridization of a terminal carbon. The Mo-allyl bond lengths are found at $2.29 \AA$ for the $\mathrm{sp}^{3}$ carbon, $2.44 \AA$ for the central carbon, and $3.24 \AA$ for the $\mathrm{sp}^{2}$ terminal carbon. The $\mathrm{sp}^{3}$ carbon to central carbon bond length is placed at $1.44 \AA$ and the central carbon to $s p^{2}$ terminal carbon at $1.40 \AA$. Unlike the 1A excited state, the overall rotational orientation of the allyl ligand remains largely unchanged from the ground state exo geometry.

Both the 1A and 2A excited states feature a substantially decreased Mo-allyl bond order, each more closely resembling a 16-electron $\operatorname{TpMo}(\mathrm{CO})_{2}\left(\eta^{1}-\mathrm{C}_{3} \mathrm{H}_{5}\right)^{\text {* }}$ species. Vibrational relaxation of the $\operatorname{TpMo}(\mathrm{CO})_{2}\left(\eta^{1}-\mathrm{C}_{3} \mathrm{H}_{5}\right)^{\star}$ like excited state may facilitate rotation along the Mo-C axis resulting in formation of either the exo or gauche rotamers upon relaxation to a $\mathrm{TpMo}(\mathrm{CO})_{2}\left(\eta^{3}-\mathrm{C}_{3} \mathrm{H}_{5}\right)$ ground state.

The results of these excited state DFT computations suggest that despite the presence an energetically accessible $\eta^{3} \rightarrow \eta^{3} \rightarrow \eta^{3}$ allyl rotation mechanism in the ground state, the photochemical exo $\leftrightarrow$ gauche isomerism observed at low temperature occurs through an excited state $\eta^{1 *}$ species. The proposed mechanism for rotameric interconversion is summarized in Scheme 5.3.

Scheme 5.3: Proposed photochemical mechanism for the allyl rotameric isomerism $\mathrm{TpM}(\mathrm{CO})_{2}\left(\eta^{3}-\mathrm{C}_{3} \mathrm{H}_{4} \mathrm{R}\right)$.

## Conclusions

Low-temperature matrix FTIR and DFT studies demonstrate that photolysis of exo-$\operatorname{TpM}(\mathrm{CO})_{2}\left(\eta^{3}-\mathrm{C}_{3} \mathrm{H}_{4} R\right)$ results in reversible rotameric isomerization to gauche-$\operatorname{TpM}(\mathrm{CO})_{2}\left(\eta^{3}-\mathrm{C}_{3} \mathrm{H}_{4} R\right)$. Excited state DFT calculations suggest that when subjected to low energy photolysis, exo- $\mathrm{TpM}(\mathrm{CO})_{2}\left(\eta^{3}-\mathrm{C}_{3} \mathrm{H}_{5}\right)$ forms an excited state species resembling 16-electron $\operatorname{TpM}(\mathrm{CO})_{2}\left(\eta^{1}-\mathrm{C}_{3} \mathrm{H}_{4} R\right)^{*}$. The photochemically generated $\operatorname{TpM}(\mathrm{CO})_{2}\left(\eta^{1}-\mathrm{C}_{3} \mathrm{H}_{4} R\right)^{*}$ excited state species may undergo vibrational relaxation to yield either of the exo or gauche forms of $\operatorname{TpM}(\mathrm{CO})_{2}\left(\mathrm{n}^{3}-\mathrm{C}_{3} \mathrm{H}_{5}\right)$.

## Experimental

All complexes were synthesized by literature procedures. ${ }^{18,19}$ The apparatus and methods for matrix photochemistry have been reported elsewhere. ${ }^{20}$

All DFT calculations were performed in the Amsterdam Density Functional (ADF2014.01) program. ${ }^{21-23}$ Electronic configurations of atoms were described by an all-electron triple- $\zeta$ Slater-type orbital basis set modified by a polarization function (TZP STO). ${ }^{24}$ Geometry optimizations and vibrational frequency calculations were performed using the GGA functional of Becke ${ }^{25}$ and Perdew ${ }^{26,27}$ using a scalar relativistic corrections within the Zeroth Order Regular Approximation (ZORA). ${ }^{28,29}$ Excited state geometries were computed using the B88P86 functional in conjunction with an all-electron triple- $\zeta$ Slater-type orbital basis set modified by a polarization function and a diffuse function (ATZP STO). The intrinsic reaction coordinate (IRC) of all calculated transition state geometries was followed to confirm the relation with the expected stationary points. Electronic excitation energies were computed using the statistical average of orbital potentials (SAOP) model. ${ }^{30,31}$

# Chapter 6: Evidence for Photochemical Linkage Isomerism of the Phenylazo Ligand in $\mathrm{M}(\mathrm{CO})_{2}\left(\mathrm{~N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}$ Cations, where $\mathrm{M}=\mathrm{Fe}$ and Ru . Published: W. A. Thornley, T. E. Bitterwolf, Eur. J. Inorg. Chem. 2015, 1946-1949. 

#### Abstract

Frozen matrix photolysis studies of $M(C O)_{2}\left(N_{2} P h\right)\left(P P h_{3}\right)_{2}$ cations, where $M$ = Fe and Ru, have revealed end-on/side-on photochemical linkage isomerism of the phenylazo ligand. Previously reported solvent dependent vibrational bands of the $\operatorname{Ru}(\mathrm{CO})_{2}\left(\mathrm{~N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}$ cation have now been identified as an equilibrium between the two linkage isomers. DFT calculations have been carried out on the end-on and sideon isomers of the iron and ruthenium complexes.

Numerous photochemical studies of metal nitrosyl compounds have established that the nitrosyl ligand undergoes linkage isomerism yielding a side-on, $\pi$-bound nitrosyl ligand or an oxygen bound isonitrosyl ligand. ${ }^{1}$ These linkage isomers may be observed directly at low temperature, but revert to the nitrogen bound nitrosyl isomer at room temperature. Two extraordinary examples of side-on nitrosyl groups stable at room temperature have been reported in the molecular structures of copper nitrite reductase enzymes. ${ }^{2,3}$

Arylazo ligands are isoelectronic with the well-known nitrosyl ligand, and like their nitrosyl counterparts, may serve as either 1 or 3 electron donors to a metal center. These 1 or 3 electron-donating isomers are referred to as doubly and singly bent, respectively, Scheme 6.1a and 6.1b. The bending in the singly bent arylazo
ligands arises due to back bonding into the $N_{2} \pi^{*}$ orbitals, breaking the degeneracy of the two $N_{2} \pi$ and $\pi^{*}$ orbitals. In the doubly bent geometry it is assumed that reduction of the phenylazo group has taken place such that the ligand is best described as an $\mathrm{N}_{2} \mathrm{Ph}$ anion. A side-on linkage isomer is also possible, Scheme 6.1c, and indeed two such derivatives, $\mathrm{CpTiCl}_{2}\left(\eta^{2}-\mathrm{N}_{2} \mathrm{Ph}\right)^{4,5}$ and $\left[\left(\mathrm{t}-\mathrm{Bu}_{2} \mathrm{P}\right)_{2} \mathrm{C}_{2} \mathrm{H}_{4}\right] \mathrm{Ni}\left(\eta^{2}-\mathrm{N}_{2} \mathrm{Ph}\right),{ }^{6}$ have been isolated. The molecular structure of the titanium compound has been reported. A bimetallic compound in which a side-on arylazo ligand serves as a bridge between two cobalt atoms is also known. ${ }^{7}$

Scheme 6.1: Known binding geometries of the phenyldiazonium ligand.

The present study of the diazonium ligand is an extension of our ongoing examination of photochemical linkage isomerism of the nitrosyl ligand. Our initial exploration of the photochemistry of compounds possessing the phenylazo ligand has led us to the well known class of arylazo compounds, $\left[\mathrm{M}(\mathrm{CO})_{2}\left(\mathrm{~N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}\right] \mathrm{BF}_{4}$ $(M=F e$ and $R u)$. The results of these studies are reported below.

The molecular structure of $\left[\mathrm{Fe}(\mathrm{CO})_{2}\left(\eta^{1}-\mathrm{N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}\right] \mathrm{BF}_{4}$ has previously been reported by Haymore and Ibers. ${ }^{8}\left[\mathrm{Fe}(\mathrm{CO})_{2}\left(\eta^{1}-\mathrm{N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}\right] \mathrm{BF}_{4}$ was found to possess a trigonal bipyramidal geometry with the carbonyl and arylazo ligands in the equatorial plane and phosphine ligands occupying the axial positions. The arylazo ligand is singly bent with a Fe-N-N bond angle of $179.2(5)^{\circ}$, and an $\mathrm{N}-\mathrm{N}-\mathrm{Ph}$ bond angle of $124.2(6)^{\circ}$. A single N-N vibrational band is observed in its infrared spectrum.

Figure 6.1: UV-Vis absorption spectrum of $\mathrm{Fe}(\mathrm{CO})_{2}\left(\eta^{1}-\mathrm{N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}$ in $\mathrm{CH}_{2} \mathrm{Cl}_{2}$.

The electronic spectrum of $\left[\mathrm{Fe}(\mathrm{CO})_{2}\left(\eta^{1}-\mathrm{N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}\right] \mathrm{BF}_{4}$ in $\mathrm{CH}_{2} \mathrm{Cl}_{2}$, Figure 6.1, has a broad absorption extending from ca. 350 nm into the visible. The results of TD-DFT calculations suggest that these low energy electronic transitions are predominantly ligand based transitions into metal $d$ and $N_{2} \pi^{*}$ antibonding orbitals. Kohn-Sham orbitals for $\left[\mathrm{Fe}(\mathrm{CO})_{2}\left(\eta^{1}-\mathrm{N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}\right]^{+}$are presented in Figure 6.2. The HOMO corresponds to a back bonding interaction between the iron and the $N_{2} \pi^{*}$ orbital. The resemblance between this orbital and Scheme 6.1a suggests that this
interaction is responsible for the development of a lone pair like orbital on the second nitrogen atom and the subsequent bending of the aryl group from linearity with the $\mathrm{N}_{2}$ group.

Photolysis of this compound in a poly(vinyl chloride) (PVC) film matrix at ca. 85 K into the broad electronic absorption (350 nm < $\lambda_{\max }<400 \mathrm{~nm}$ ), Figure 6.3a, results in bleaching of the parent carbonyl and arylazo ligand bands and growth of new bands belonging to the photoproduct. Two new carbonyl bands are shifted to slightly higher energy in the photoproduct. ${ }^{15} \mathrm{~N}$ labeling of the terminal nitrogen in the arylazo ligand, Figure 6.3b, established that the new bands at 1628 and $1570 \mathrm{~cm}^{-1}$ of the unlabeled sample are coupled to the $\mathrm{N}-\mathrm{N}$ vibrational mode of the arylazo ligand. The absorptions at 1589 and $1579 \mathrm{~cm}^{-1}$ of the parent complex, as well as additional bands below $1400 \mathrm{~cm}^{-1}$ (not shown), are assigned to phenyl ring vibrational modes that are shifted as a result of the photochemical transformation but are not necessarily coupled to the $\mathrm{N}-\mathrm{N}$ vibration. $\mathrm{Fe}(\mathrm{CO})_{2}\left(\eta^{1}-\mathrm{N}_{2}-4-\right.$ $\left.\mathrm{C}_{6} \mathrm{H}_{4} \mathrm{~F}\right)\left(\mathrm{PPh}_{3}\right)_{2} \mathrm{BF}_{4}$ and its ${ }^{15} \mathrm{~N}$ isotopomer were also photolyzed and exhibited similar spectral changes. The new $\mathrm{N}-\mathrm{N}$ phenylazo vibrational bands fall in the same region as those of the reported side-on arylazo derivatives, $\mathrm{CpTiCl}_{2}\left(\eta^{2}-\mathrm{N}_{2} \mathrm{Ph}\right), 1550 \mathrm{~cm}^{-1}$, and (dtbpe)Ni( $\left.\eta^{2}-\mathrm{N}_{2} \mathrm{Ph}\right), 1602 \mathrm{~cm}^{-1}$, therefore we assign the second isomer to an analogous side-on arylazo isomer.

Figure 6.2: Kohn-Sham orbitals of $\mathrm{Fe}(\mathrm{CO})_{2}\left(\eta^{1}-\mathrm{N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}{ }^{+}$.

Figure 6.3: Photolysis of $\mathrm{Fe}(\mathrm{CO})_{2}\left(\eta^{1}-\mathrm{N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}$ (a) and its ${ }^{15} \mathrm{~N}$ isotopomer (b) in a PVC film matrix at ca. 90 K . Spectra are the difference of a 10 min photolysis (350 $n m<\lambda_{\max }<400 \mathrm{~nm}$ ) minus a 10 min photolysis $\left(\lambda_{\max }=500 \pm 35 \mathrm{~nm}\right)$.

Table 6.1: Calculated energies ( $\mathrm{kcal} \mathrm{mol}^{-1}$ ) and observed and calculated carbonyl and aryldiazonium vibrational frequencies $\left(\mathrm{cm}^{-1}\right)$ for $\mathrm{Fe}(\mathrm{CO})_{2}\left(\eta^{1}-\mathrm{N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}$ and $\mathrm{Fe}(\mathrm{CO})_{2}\left(\eta^{1}-\mathrm{N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}$, calculated intensities are given in parentheses $\left(\mathrm{km} \mathrm{mol}^{-1}\right)$.

The results of DFT calculations carried on the $\eta^{1}$ and $\eta^{2}$ linkage isomers of $\left[\mathrm{Fe}(\mathrm{CO})_{2}\left(\mathrm{~N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}\right]^{+}$are summarized in Table 6.1. In the side-on orientation, vibrational coupling between the $\mathrm{N}-\mathrm{N}$ stretching vibration and phenyl bending motions gives rise to two weak bands that correspond to the two bands observed in the matrix spectra at $1628 \mathrm{~cm}^{-1}$ and $1570 \mathrm{~cm}^{-1}$. The calculated phenyl azo vibrational frequencies are in good agreement with the observed frequencies. Further, these calculations reproduce the direction of the carbonyl vibrational band shifts observed in moving from the $\eta^{1}$ to $\eta^{2}$ isomer. $\left[\mathrm{Fe}(\mathrm{CO})_{2}\left(\eta^{1}-\mathrm{N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}\right]^{+}$is calculated to lie 8.3 kcal $\mathrm{mol}^{-1}$ lower in energy than its $\left[\mathrm{Fe}(\mathrm{CO})_{2}\left(\mathrm{n}^{2}-\mathrm{N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}\right]^{+}$ isomer.

## Frozen Matrix Photochemistry of $\left[\mathrm{Ru}(\mathrm{CO})_{2}\left(\mathbf{N}_{2} \mathbf{P h}\right)\left(\mathrm{PPh}_{3}\right)_{2}\right] \mathrm{BF}_{4}$

The molecular structure of the $\left[\mathrm{Ru}(\mathrm{CO})_{2}\left(\mathrm{~N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}\right]^{+}$cation has not been reported. Haywood and Ibers noted an unusually complex pattern of isotopically sensitive vibrational bands for this compound. ${ }^{9}$ In contrast to the iron compound where a single $\mathrm{N}-\mathrm{N}$ vibrational band was observed, three vibrational bands were found to be sensitive to ${ }^{15} \mathrm{~N}$ substitution of the phenylazo ligand. The highest energy of these $\mathrm{N}-\mathrm{N}$ vibrational modes was assigned to an end-on, $\eta^{1}$, arylazo group, while the two additional bands were attributed to a second isomer that was tentatively assigned to a doubly bent arylazo group. One of these bands was assumed to arise from coupling of phenyl and $\mathrm{N}_{2}$ vibrational modes. Only one set of carbonyl bands was observed. The ratio of the two isomers was found to be dependent upon the
sample medium; the end-on isomer being favored in Nujol mulls, while the second isomer was favored in $\mathrm{CH}_{2} \mathrm{Cl}_{2}$ solutions.

While $\left[\mathrm{Ru}(\mathrm{CO})_{2}\left(\mathrm{~N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}\right] \mathrm{BF}_{4}$ is stable as a microcrystalline solid, its solutions in halocarbon solvents are both air and light sensitive. Samples for photolysis had to be prepared in the dark under a flow of purified nitrogen to evaporate the 1,1,2,2-tetrachloroethane solvent used for casting the PVC films used in the low-temperature photolysis experiments. Even under stringent conditions a trace of a second species was always evident in the samples. Fortunately, this species did not undergo photolysis at visible wavelengths.

Figure 6.4. Photolysis of $\mathrm{Ru}(\mathrm{CO})_{2}\left(\eta^{1}-\mathrm{N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}$ (a) and its ${ }^{15} \mathrm{~N}$ isotopomer (b) in a PVC film matrix at ca. 90 K . Spectra are the difference of a 10 min photolysis $\left(\lambda_{\max }\right.$ $=450 \pm 35 \mathrm{~nm})$ minus a 10 min photolysis $\left(\lambda_{\max }=500 \pm 35 \mathrm{~nm}\right)$. Bands whose positions do not vary upon isotopic substitution are only marked in 6.4a.

The IR spectrum of $\left[\mathrm{Ru}(\mathrm{CO})_{2}\left(\mathrm{~N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}\right] \mathrm{BF}_{4}$ in PVC exhibits no absorptions in the $1700-1600 \mathrm{~cm}^{-1}$ region that may be assigned to an $\eta^{1}-\mathrm{N}_{2} \mathrm{Ph}$ species. Small features could be observed in the $1625-1500 \mathrm{~cm}^{-1}$ region where vibrational modes arising from the phenyl rings as well as bands of the second isomer reported by Haymore and Ibers would be expected. Upon visible photolysis ( $\lambda_{\max }=450 \pm 35 \mathrm{~nm}$ ) of this compound, Figure 6.4a, new carbonyl absorptions, as well as an absorption at $1696 \mathrm{~cm}^{-1}$ were found to grow in. The carbonyl bands were slightly lower in energy than those of the initial species. In the spectral region between 1625-1500 $\mathrm{cm}^{-1}$ bands at 1612 and $1560 \mathrm{~cm}^{-1}$ were found to decrease in intensity while the intensity of bands at 1593 and $1573 \mathrm{~cm}^{-1}$ increased. Photolysis of the ${ }^{15} \mathrm{~N}$ isotopomer, Figure 6.4 b , established that the bands at 1612 and $1560 \mathrm{~cm}^{-1}$ and the new, strong absorption at $1696 \mathrm{~cm}^{-1}$ were associated with the $\mathrm{N}-\mathrm{N}$ vibrational mode of the arylazo ligand. We reject the possibility that the new isomeric species has the doubly bent arylazo group suggested by Haymore and lbers since the transformation from a singly bent to doubly bent ligand implies a formal oxidation of the metal. The relatively small shifts in the carbonyl stretching frequencies are not consistent with a dramatic shift of electron density away from the metal.

Comparison of Figures 6.3 and 6.4 clearly establish that the iron sample undergoes a photochemical transformation from the $\eta^{1}-N_{2} \mathrm{Ph}$ isomer to a new isomer, while the ruthenium compound displays exactly the opposite behavior. DFT calculations place $\left[\mathrm{Ru}(\mathrm{CO})_{2}\left(\eta^{2}-\mathrm{N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)\right]^{+}$just $1.3 \mathrm{kcal} \mathrm{mol}^{-1}$ higher in energy than $\left[\mathrm{Ru}(\mathrm{CO})_{2}\left(\eta^{1}-\mathrm{N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}\right]^{+}$, consistent with the observed solvent dependent isomerization that would require a near barrierless interconversion.

Table 6.2. Calculated energies ( $\mathrm{kcal} \mathrm{mol}^{-1}$ ) and observed and calculated carbonyl and aryldiazonium vibrational bands $\left(\mathrm{cm}^{-1}\right)$ for $\mathrm{Ru}(\mathrm{CO})_{2}\left(\eta^{1}-\mathrm{N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}$ and $\operatorname{Ru}(C O)_{2}\left(\eta^{1}-\mathrm{N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}$, calculated intensities are given in parentheses $\left(\mathrm{km} \mathrm{mol}^{-1}\right)$.

## Conclusions

Photochemical linkage isomerism is well established for the nitrosyl ligand and appears to also be possible for at least a few examples of the isoelectronic phenylazo ligand. Interestingly, it appears that the phenylazo ligand in $\mathrm{Ru}(\mathrm{CO})_{2}\left(\mathrm{~N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}$ may flip from one geometry to the other at room temperature under the influence of solvent. Unlike the case of the nitrosyl ligand where the lifetime of linkage isomers at room temperature is fleetingly small, the side-on phenylazo ligand may be sufficiently long lived to exhibit chemistry distinct from that of the endon isomer.

## Experimental

$\left[\mathrm{Fe}(\mathrm{CO})_{2}\left(\mathrm{n}^{1}-\mathrm{N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2} \mathrm{BF}_{4},{ }^{10} \quad\left[\mathrm{Fe}(\mathrm{CO})_{2}\left(\mathrm{\eta}^{1}-\mathrm{N}_{2} \mathrm{Ph}\right)\left[\left(4-\mathrm{F}-\mathrm{C}_{6} \mathrm{H}_{4}\right)_{3} \mathrm{P}_{2}\right\} \mathrm{BF}_{4},{ }^{10} \quad\right.\right.$ and $\left[\mathrm{Ru}(\mathrm{CO})_{2}\left(\mathrm{~N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}\right] \mathrm{BF}_{4},{ }^{9}$ were prepared by literature procedures. The apparatus and methods for matrix photochemistry have been reported elsewhere. ${ }^{11}$

All DFT calculations were performed in the Amsterdam Density Functional (ADF2013.01) program. ${ }^{12-14}$ Electronic configurations of atoms were described by an all-electron triple- Slater-type orbital basis set modified by a polarization function (TZP STO). ${ }^{15}$ Geometry optimizations and vibrational frequency calculations were performed using the GGA functional of Becke ${ }^{16}$ and Perdew ${ }^{17,18}$ utilizing a singlecomponent scalar relativistic correction within the zeroth order regular approximation (ZORA). ${ }^{19,20}$ Vertical electronic excitation energies were computed with the statistical average of orbital potentials (SAOP) model. ${ }^{21,22}$

# Chapter 7: Photolysis of Isoelectronic Ruthenium Nitrosyl and Diazonium Complexes in Frozen PVC Matrices. Retention of Dinitrogen on Ruthenium Following Photochemical Phenyl Radical Loss. 

Published: W. A. Thornley, T. E. Bitterwolf, Eur. J. Inorg. Chem. 2016, 464-468.

#### Abstract

Photolysis of $\mathrm{RuCl}_{3}\left(\eta^{1}-\mathrm{NO}\right)\left(\mathrm{PPh}_{3}\right)_{2}$ in polyvinyl chloride (PVC) matrices at $85 K$ results in reversible linkage isomerism of the nitrosyl ligand to form the isonitrosyl complex $\mathrm{RuCl}_{3}\left(\eta^{1}-\mathrm{ON}\right)\left(\mathrm{PPh}_{3}\right)_{2}$. Metal-to-ligand charge-transfer (MLCT) excitation of the isoelectronic phenylazo complex, $R u C_{3}\left(\eta^{1}-N_{2} P h\right)\left(P P h_{3}\right)_{2}$, has previously been shown to result in generation of the phenyl radical, presumably through decomposition a photogenerated diazenyl radical. Examination of this photolysis in a PVC matrix at cryogenic temperatures has permitted direct observation of an isotopically sensitive product band that may be assigned to a 17electron ruthenium dinitrogen species, suggesting that this photochemical decomposition does not proceed through formation of a diazenyl intermediate but through homolytic cleavage of the parent diazonium complex to give the phenyl radical and the 17-electron $\mathrm{RuCl}_{3}\left(\eta^{1}-\mathrm{N}_{2}\right)\left(P P h_{3}\right)_{2}$.

The ability of the nitrosyl ligand to undergo linkage isomerism following photolysis to yield side-on, $\pi$-bound isomers and oxygen bound, isonitrosyl isomers is well known. ${ }^{[1]}$ These isomers may be generated and characterized at low temperature, but rapidly revert to the nitrogen bound nitrosyl isomer at non-

cryogenic temperatures. Like the nitrosyl ligand, arylazo ligands may act as either 3 or 1 electron donors to a metal; these isomers are referred to as singly and doubly bent, respectively, Scheme 7.1a and 7.1b. A side-on linkage isomer is also known, Scheme 7.1c, and several such derivatives, have been isolated. ${ }^{[2-4]}$ Despite the similarities between the nitrosyl and arylazo ligands, the photochemistry of arylazo complexes has largely gone unexplored since the discovery of this class of compounds by King and Bisnette in 1964. ${ }^{[5,6]}$.

a

b

c

Scheme 7.1: Known coordination modes of the phenyldiazonium ligand. (a) $\eta^{1}-$ singly-bent, (b) $\eta^{1}$ - doubly-bent, (c) $\eta^{2}$.

Our attention has recently turned to the photochemistry of diazonium complexes as an extension of our ongoing study of the nitrosyl ligand. Initial findings from this work indicate that like the nitrosyl ligand, diazonium ligands may also undergo photochemical linkage isomerism. ${ }^{[7]}$ Prior to this work, the only examination of the photochemistry of a phenylazo metal complex that we are aware of is the solution photochemistry of $\mathrm{RuCl}_{3}\left(\eta^{1}-\mathrm{N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}$ performed by Kunkely and Vogler. ${ }^{[8]}$ In this work, it is reported that photolysis of $\mathrm{RuCl}_{3}\left(\eta^{1}-\mathrm{N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}$ in
acetonitrile results in formation of $\mathrm{RuCl}_{3}(\mathrm{NCMe})\left(\mathrm{PPh}_{3}\right)_{2}, \mathrm{~N}_{2}$, and biphenyl with $\Phi=7$ $\times 10^{-3}$ at $\lambda_{\text {irr }}=520 \mathrm{~nm}$. The proposed mechanism for production of $\mathrm{N}_{2}$ and biphenyl involves metal-to-ligand charge-transfer (MLCT) to the phenylazo ligand resulting in loss of a neutral phenyldiazenyl radical. The phenyldiazenyl radical is well known to decompose to yield $\mathrm{N}_{2}$ and phenyl radical which may then couple to produce the biphenyl, Scheme 7.2. ${ }^{[9-21]}$

Scheme 7.2: Mechanism for phenyl radical formation proposed by Kunkely and Vogler.

In light of the report by Kunkely and Vogler, we thought it fruitful to carry out low temperature photolyses of $\mathrm{RuCl}_{3}\left(\mathrm{n}^{1}-\mathrm{N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}$ and its nitrosyl analogue with the expectation of observing a side-on, $\mathrm{RuCl}_{3}\left(\eta^{2}-\mathrm{N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}$ photointermediate that we anticipated may be a precursor to diazenyl radical loss. The surprising results of these studies are reported below.

## Photolysis of $\mathrm{RuCl}_{3}\left(\mathbf{\eta}^{\mathbf{1}}-\mathrm{NO}\right)\left(\mathrm{PPh}_{3}\right)_{2}$

$\operatorname{RuCl}_{3}(\mathrm{NO}) \mathrm{L}_{2}$ derivatives are readily prepared by reaction of an appropriate ligand with $\left[\mathrm{RuCl}_{3}(\mathrm{NO})\right]_{n}$ in ethanol. ${ }^{[22]} \mathrm{RuCl}_{3}(\mathrm{NO})\left(\mathrm{PPh}_{3}\right)_{2}$ has a strong charge transfer band at $342 \mathrm{~nm}\left(\varepsilon=15,200 \mathrm{M}^{-1} \mathrm{~cm}^{-1}, \mathrm{CH}_{2} \mathrm{Cl}_{2}\right)$ with a tail that extends to ca. 510 nm . The relatively high nitrosyl stretching frequency of $\mathrm{RuCl}_{3}(\mathrm{NO})\left(\mathrm{PPh}_{3}\right)_{2}$ at $1873 \mathrm{~cm}^{-1}$ is
consistent with other Ru" complexes. By way of comparison, the related Ru" nitrosyl species $\mathrm{Na}_{2}\left[\mathrm{Ru}(\mathrm{CN})_{5} \mathrm{NO}\right] \cdot 2 \mathrm{H}_{2} \mathrm{O}$ and $\mathrm{K}_{2}\left[\mathrm{RuCl}_{5}(\mathrm{NO})\right]$ exhibit nitrosyl stretching modes at 1932 and $1921 \mathrm{~cm}^{-1}$, respectively ${ }^{[23,24]}$

Figure 7.1. Difference spectra following photolysis of $\mathrm{RuCl}_{3}\left(\mathrm{PPh}_{3}\right)_{2}(\mathrm{NO})$ at 85 K in PVC: (a) sample following 10 min photolysis ( $\lambda_{\text {lrr }}=500 \pm 50 \mathrm{~nm}$ ) minus sample before photolysis. (b) Sample after $10 \min \lambda_{\mathrm{lr}}>525 \mathrm{~nm}$ back photolysis minus $\lambda_{\mathrm{lrr}}=$ $500 \pm 50 \mathrm{~nm}$ irradiated sample.

Photolysis of $\mathrm{RuCl}_{3}(\mathrm{NO})\left(\mathrm{PPh}_{3}\right)_{2}$ in PVC matrices at 85 K with $\lambda_{\text {irr }}=500 \pm 50 \mathrm{~nm}$ results in bleaching of the parent nitrosyl band at $1873 \mathrm{~cm}^{-1}$ and appearance of a photoproduct absorption at $1748 \mathrm{~cm}^{-1}\left(\Delta \mathrm{v}=125 \mathrm{~cm}^{-1}\right)$, Figure 7.1a. Photolysis at shorter wavelengths, $330<\lambda_{\text {irr }}<400 \mathrm{~nm}$, increases the extent of conversion between these two species but does not result in the appearance of any additional product
bands. Long wavelength back-photolysis of $330<\lambda_{\text {irr }}<500 \mathrm{~nm}$ photolyzed samples with $\lambda_{\text {irr }}>525 \mathrm{~nm}$, Figure 7.1b, cleanly reverses the transformation. The photoproduct band is shifted $125 \mathrm{~cm}^{-1}$ lower in energy relative to the parent nitrosyl band, consistent with formation of the isonitrosyl linkage isomer. ${ }^{[24]}$

Theoretical models ${ }^{[25,26]}$ of nitrosyl linkage isomerism suggest that their interconversion are stepwise in the order: $\mathrm{M}-\mathrm{NO} \nLeftarrow \mathrm{M}-\left(\eta^{2}-\mathrm{NO}\right) \nLeftarrow \mathrm{M}-\mathrm{ON}$. In the current case, the failure to observe a side-on nitrosyl species argues for an overlap of the electronic absorption bands of the side-on nitrosyl species with those of the starting nitrosyl compound, thus giving rise to the isonitrosyl species with a low equilibrium population of the side-on isomer. The low-temperature matrix photochemistry of $\mathrm{RuCl}_{3}(\mathrm{NO})\left(\mathrm{PPh}_{3}\right)_{2}$ is summarized in Scheme 7.3.

Scheme 7.3: Observed photochemical behavior of $\mathrm{RuCl}_{3}\left(\mathrm{NO}_{( }\left(\mathrm{PPh}_{3}\right)_{2}\right.$ in PVC matrices at 85 K .

## Photolysis of $\mathrm{RuCl}_{3}\left(\mathbf{\eta}^{1}-\mathbf{N}_{2} \mathbf{P h}\right)\left(\mathrm{PPh}_{3}\right)_{2}$

Acetonitrile solutions of $\mathrm{RuCl}_{3}\left(\eta^{1}-\mathrm{N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}$ are reported to have two absorptions in the visible ( 520 nm , sh, $\varepsilon=120 \mathrm{M}^{-1} \mathrm{~cm}^{-1}$ and 420 nm , sh, $\varepsilon=600 \mathrm{M}^{-1}$ $\left.\mathrm{cm}^{-1}\right)$ and a strong charge transfer band in the UV $\left(310 \mathrm{~cm}^{-1}, 12,000 \mathrm{M}^{-1} \mathrm{~cm}^{-1}\right)$ that
parallels the band observed in the nitrosyl derivative. ${ }^{[8]}$ The infrared spectrum exhibits an intense $N=N$ vibrational mode of the diazonium ligand at $1872 \mathrm{~cm}^{-1}$, consistent with a singly-bent, $\eta^{1}$ coordination mode.

Irradiation of $\mathrm{RuCl}_{3}\left(\eta^{1}-\mathrm{N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}$ in PVC matrices at 85 K using wavelengths from 550 to 245 nm results in a single photochemical process; bleaching of the phenylazo band at $1872 \mathrm{~cm}^{-1}$ and appearance of a species possessing a low-intensity absorption at $2170 \mathrm{~cm}^{-1}$, Figure 7.3 a. Photolysis of the ${ }^{15} \mathrm{~N}$ isotopomer, $\mathrm{RuCl}_{3}\left(\mathrm{\eta}^{1}-{ }^{15} \mathrm{NNPh}\right)\left(\mathrm{PPh}_{3}\right)_{2}$, Figure 7.3 b , bleaches the parent phenylazo $\mathrm{N}=\mathrm{N}$ band at $1845 \mathrm{~cm}^{-1}$ and shifts the resulting product band to $2135 \mathrm{~cm}^{-1}$, consistent with this photoproduct possessing an end-on $\mathrm{N}_{2}$ oscillator. Dinitrogen complexes of ruthenium are known to have $\mathrm{N}_{2}$ vibrational frequencies from 2100 $2182 \mathrm{~cm}^{-1}$, with the closely related $\left(\mathrm{PPh}_{3}\right)_{2} \mathrm{CIRu}(\mu-\mathrm{Cl})_{3} \mathrm{Ru}\left(\mathrm{PPh}_{3}\right)_{2}\left(\mathrm{~N}_{2}\right)$ having an $\mathrm{N}_{2}$ stretching mode at $2165 \mathrm{~cm}^{-1} .{ }^{27}$ Low energy ( $\lambda_{\text {Irr }}>590 \mathrm{~nm}$ ) back-photolysis of the irradiated sample did not result in reversion of the photoproduct to the parent complex, and annealing of the matrix to 160 K resulted only in depletion of the 2170 $\mathrm{cm}^{-1}$ photoproduct absorption with no evidence for reversion to the parent diazonium species.

Figure 7.2. Difference spectra of the photolysis of $\mathrm{RuCl}_{3}\left(\mathrm{PPh}_{3}\right)_{2}\left(\mathrm{~N}_{2} \mathrm{Ph}\right)$ (a) and its
${ }^{15}$ NNPh isotopomer (b). Sample after 10 min photolysis $\left(\lambda_{1 r r}=500 \pm 50 \mathrm{~nm}\right)$ minus sample before photolysis.

In light of the work of Kunkely and Vogler that established generation of phenyl radicals in the solution photochemistry of $\mathrm{RuCl}_{3}\left(\eta^{1}-\mathrm{N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2},{ }^{8}$ and the results of our low-temperature photolysis experiments demonstrating the formation of a Ruthenium dinitrogen complex following photolysis, we propose photochemical homolysis of the arylazo N-Ph bond to yield a 17-electron $\mathrm{RuCl}_{3}\left(\eta^{1}-\mathrm{N}_{2}\right)\left(\mathrm{PPh}_{3}\right)_{2}$ and the phenyl radical. Though the phenyl radical has been observed in frozen inert gas matrices, ${ }^{28,29}$ we are unable to make any spectral assignments directly attributable to this species in our 85 K PVC matrix experiments. This absence may be the product of the broad spectral bandwidths observed in PVC matrices relative to those in gas
matrices, as well as a high degree of spectral overlap with $\mathrm{PPh}_{3}$ phenyl ring vibrational modes, resulting in a failure of these product vibrational bands to resolve. Moreover, given the high reactivity of the phenyl radical, any phenyl radical that is photochemically generated may undergo secondary reaction with the PVC matrix material through halogen abstraction or addition to any residual unsaturated bonds of the polymer. Such reactions would effectively "trap" the phenyl radical, and help facilitate observation of the $\mathrm{RuCl}_{3}\left(\mathrm{\eta}^{1}-\mathrm{N}_{2}\right)\left(\mathrm{PPh}_{3}\right)_{2}$ radical by preventing recombination of the radical pair. Regardless, the ultimate fate of the phenylazo phenyl group remains elusive under these experimental conditions.

To better understand the observed matrix photochemistry of $\mathrm{RuCl}_{3}\left(\eta^{1}-\right.$ $\left.\mathrm{N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}$, a DFT investigation was carried out. Geometric parameters from these calculations are summarized in Table 7.1. Calculations carried out on the products of $\mathrm{N}-\mathrm{Ph}$ bond homolysis, 17-electron $\mathrm{RuCl}_{3}\left(\eta^{1}-\mathrm{N}_{2}\right)\left(\mathrm{PPh}_{3}\right)_{2}$ and the phenyl radical, predict an $\mathrm{N}_{2}$ vibrational frequency of $2194 \mathrm{~cm}^{-1}$ for the dinitrogen photoproduct, in good agreement with the species observed in the matrix photochemistry experiments. The calculated $\mathrm{N}=\mathrm{N}$ vibrational mode of the parent diazonium complex was slightly underestimated relative to the experimental value at $1825 \mathrm{~cm}^{-1}$ and 1872 $\mathrm{cm}^{-1}$, respectively. Fully consistent with a low-energy photochemical homolysis reaction, the change in free energy for $\mathrm{N}-\mathrm{Ph}$ bond cleavage in $\mathrm{RuCl}_{3}\left(\mathrm{n}^{1}-\mathrm{N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}$ to give $\mathrm{RuCl}_{3}\left(\mathrm{\eta}^{1}-\mathrm{N}_{2}\right)\left(\mathrm{PPh}_{3}\right)_{2}$ and the phenyl radical is calculated to be just 14.7 kcal $\mathrm{mol}^{-1}$. Ph-N heterolysis pathways resulting in formation of either cationic or anionic $\operatorname{RuCl}_{3}\left(\eta^{1}-\mathrm{N}_{2}\right)\left(\mathrm{PPh}_{3}\right)_{2}$ species were both highly energetically disfavored. Based on the large energetic expense of either heterolysis pathways, as well as the evidence for
phenyl radical formation in solution studies, we dismiss both the cationic and anionic forms of $\mathrm{RuCl}_{3}\left(\eta^{1}-\mathrm{N}_{2}\right)\left(\mathrm{PPh}_{3}\right)_{2}$ as the possible dinitrogen species observed in the matrix photochemistry experiments.

Table 7.1. Calculated bond lengths $(\AA)$ and angles ( ${ }^{\circ}$ ) for $\mathrm{RuCl}_{3}\left(\eta^{1}-\mathrm{N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}$, $\operatorname{RuCl}_{3}\left(\eta^{1}-\mathrm{N}_{2}\right)\left(\mathrm{PPh}_{3}\right)_{2}$, and observed values for $\mathrm{RuCl}_{3}\left(\eta^{1}-\mathrm{N}_{2} \mathrm{Tol}\right)\left(\mathrm{PPh}_{3}\right)_{2}$.

[a] From ref. ${ }^{30}$

To understand what electronic transitions contribute to the observed photochemical behaviour, the electronic structure of $\mathrm{RuCl}_{3}\left(\eta^{1}-\mathrm{PhN}_{2}\right)\left(\mathrm{PPh}_{3}\right)_{2}$ was analyzed. The computed Kohn-Sham frontier orbitals of $\mathrm{RuCl}_{3}\left(\eta^{1}-\mathrm{PhN}_{2}\right)\left(\mathrm{PPh}_{3}\right)_{2}$ are presented in Figure 7.3. The HOMO and $\mathrm{HOMO}-1$ orbitals are dominated by $\mathrm{Cl} p$ and $R u d_{x y}$ and $d_{x z}$ orbitals. The HOMO -1 exhibits a degree of back-bonding between ruthenium and an $N_{2} \pi^{\star}$ orbital. The resemblance that this molecular orbital bears towards Scheme 7.1a is indicative of this interaction developing the lone pair like orbital on the second diazonium nitrogen atom and the subsequent bending of the aryl group from linearity with the $\mathrm{N}_{2}$ group. The LUMO and LUMO + 1 are predominantly antibonding in character composed of ruthenium d orbitals and diazonium $\mathrm{N}_{2} \pi^{\star}$ orbitals. MLCT, corresponding to a transition from either the HOMO - 1 or HOMO to the LUMO or LUMO + 1, would result in a formally reduced diazonium ligand, which would be expected to result in a doubly-bent diazonium coordination mode in the excited state, Scheme 7.1b.

LUMO + 1

HOMO

Figure 7.3: Frontier orbitals of $\mathrm{RuCl}_{3}\left(\mathrm{\eta}^{1}-\mathrm{N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}$

Time-dependent DFT (TD-DFT) calculations suggest that the lowest energy electronic transitions are composed of HOMO $\rightarrow$ LUMO and HOMO - $1 \rightarrow$ LUMO transitions at 1.687 and 1.798 eV , respectively. Optimizing for the first excited state geometry results in the expected doubly-bent diazonium coordination mode with the Ru-N-N angle decreasing from $176.8^{\circ}$ in the ground state to $150.5^{\circ}$ in the 1 A excited state, Figure 7.4. Surprisingly, only a negligible increase of the $\mathrm{N}-\mathrm{Ph}$ bond length occurs, changing from $1.414 \AA$ in the ground state to $1.436 \AA$ in the 1 A excited state, despite photolysis into the lowest energy transitions resulting in loss of a phenyl
radical. This may suggest that $\mathrm{N}-\mathrm{Ph}$ homolysis is not directly occurring in the excited state, but rather as the result of vibrational relaxation of the excited state species.

Figure 7.4. Calculated 1 A excited state geometry of $\mathrm{RuCl}_{3}\left(\eta^{1}-\mathrm{N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}$

## Conclusions

Photolysis of the nitrosyl complex $\mathrm{RuCl}_{3}\left(\eta^{1}-\mathrm{NO}\right)\left(\mathrm{PPh}_{3}\right)_{2}$ in PVC matrices at 85 K results in simple linkage isomerism to yield the isonitrosyl complex, $\mathrm{RuCl}_{3}\left(\eta^{1}-\right.$ $\mathrm{ON})\left(\mathrm{PPh}_{3}\right)_{2}$. For the isoelectronic phenyldiazonium complex, $\mathrm{RuCl}_{3}\left(\eta^{1}-\mathrm{N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}$, the appearance of an isotopically sensitive vibrational band in the metal dinitrogen stretching region following photolysis in PVC matrices at 85 K , evidence of phenyl radical formation in solution studies, and the results of DFT computations, support a photomechanism involving homolysis of the $\mathrm{N}-\mathrm{Ph}$ bond of the diazonium ligand following low-energy MLCT excitation with no evidence for linkage isomerism. Though excited-state DFT geometry optimizations show only a marginal elongation of the N-Ph bond, cleavage of this bond may occur as a result of relaxation of a
vibrationally hot, excited state species. The proposed mechanism for this reaction is presented in Scheme 7.4.

Scheme 7.4: Proposed photolytic $\mathrm{N}-\mathrm{Ph}$ bond homolysis of $\mathrm{RuCl}_{3}\left(\eta^{1}-\mathrm{N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}$

While phenyldiazonium salts are well known to undergo reductive dediazotization by a variety of metal reducing agents to yield aryl radicals, $\mathrm{RuCl}_{3}\left(\eta^{1}-\right.$ $\left.\mathrm{N}_{2} \mathrm{Ph}\right)\left(\mathrm{PPh}_{3}\right)_{2}$ appears to be a unique example in which an isolable metal phenylazo complex may undergo photochemical charge transfer initiated phenyl radical loss with retention (at least at cryoscopic temperatures) of the dinitrogen group.

## Experimental

$\mathrm{RuCl}_{3}\left(\mathrm{PPh}_{3}\right)_{2}(\mathrm{NO})$ and $\mathrm{RuCl}_{3}\left(\mathrm{PPh}_{3}\right)_{2}\left(\mathrm{~N}_{2} \mathrm{Ph}\right)$ were prepared by literature methods. ${ }^{22,30}$ The apparatus and methods for matrix photochemistry have been reported elsewhere. ${ }^{31}$ All DFT calculations were performed in the Amsterdam Density

Functional (ADF2014.02) program. ${ }^{32-34}$ Electronic configurations of atoms were described by an all-electron triple- $\zeta$ Slater-type orbital basis set modified by a polarization function (TZP STO). ${ }^{35}$ Geometry optimizations and vibrational frequency calculations were performed using the GGA functional of Becke ${ }^{36}$ and Perdew ${ }^{37,38}$ utilizing a single-component scalar relativistic correction within the zeroth order regular approximation (ZORA)..$^{39,40}$ Vertical electronic excitation energies were computed with the statistical average of orbital potentials (SAOP) model. ${ }^{41,42}$

Figure A3: Calculated SOC-B88P86 TDDFT Electronic Spectrum of 1e

Appendix B: Additional Spectra for "Chapter 3: Revisiting the Photochemistry of Vaska's $\mathrm{O}_{2}$ Complex: Competitive Reductive and Non-Reductive Elimination Reactions"

Figure B1: Observed color change following $350 \pm 70 \mathrm{~nm}$ photolysis of Ir ${ }^{\text {l'I }} \mathrm{Cl}(\mathrm{CO}) \mathrm{O}_{2}\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$ in $\mathrm{CH}_{2} \mathrm{Cl}_{2}$ under $20 \mathrm{PSI} \mathrm{O}_{2}$.

Figure B2: Observed UV-Vis spectral evolution of $\operatorname{lr}{ }^{\prime \prime \prime} \mathrm{Cl}(\mathrm{CO}) \mathrm{O}_{2}\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$ in toluene under $20 \mathrm{PSI} \mathrm{O}_{n}$ at intervals between 0-360 minutes durina $350 \pm 70 \mathrm{~nm}$ photolvsis.

Figure B3: UV-Vis spectra of $\operatorname{Ir}{ }^{\prime \prime} \mathrm{Cl}(\mathrm{CO}) \mathrm{O}_{2}\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$ and $\operatorname{Ir} \mathrm{Cl}(\mathrm{CO})\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$ in toluene.

Figure B4: Ir"'Cl( $\left.{ }^{13} \mathrm{CO}\right) \mathrm{O}_{2}\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$ (black trace). ${ }^{31} \mathrm{P} \mathrm{NMR}\left(120 \mathrm{MHz}\right.$, $\left[\mathrm{D}_{2}\right]$ Methylene Chloride, $30^{\circ} \mathrm{C}$ ): $\delta=4.07$ ( $\mathrm{d}, \mathrm{J}^{\mathrm{P}-13 \mathrm{CO}}=8.70 \mathrm{~Hz}$; ipso).

Photolysis product - $\mathrm{OPPh}_{3}$ (blue trace). ${ }^{31} \mathrm{P} \mathrm{NMR}\left(120 \mathrm{MHz},\left[\mathrm{D}_{2}\right]\right.$ Methylene Chloride, $30^{\circ} \mathrm{C}$ ): $\delta=27.19$.

## Vaska's $\mathrm{O}_{2}$ Complex in $\mathrm{CD}_{2} \mathrm{Cl}_{2},{ }^{13} \mathrm{CO}$ enriched

Figure B5: $\operatorname{lr}{ }^{I \prime \prime} \mathrm{Cl}\left({ }^{13} \mathrm{CO}\right) \mathrm{O}_{2}\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2} .{ }^{13} \mathrm{C}$ NMR $\left(75 \mathrm{MHz},\left[\mathrm{D}_{2}\right]\right.$ Methylene Chloride, $\left.30{ }^{\circ} \mathrm{C}\right)$ : $\delta=127.85$ (t, J = 29.05 Hz; ipso), 128.53 (t, J = 5.31 Hz; ortho), 131.33 (t, J = 0.91 Hz ; para), 134.83 (t, J = 5.57 Hz; meta), 168.98 (t, J = $\left.8.71 \mathrm{~Hz} ;{ }^{13} \mathrm{CO}\right)$

12 Hour Photolysis of Vaska's $\mathrm{O}_{2}$ Complex in $\mathrm{CD}_{2} \mathrm{Cl}_{2},{ }^{13} \mathrm{CO}$ enriched

Figure B6: Photolysis products $-\mathrm{CO}_{2} / \mathrm{OPPh}_{3} .{ }^{13} \mathrm{C}$ NMR $\left(75 \mathrm{MHz}\right.$, $\left[\mathrm{D}_{2}\right]$ Methylene Chloride, $30^{\circ} \mathrm{C}$ ): $\delta=125.09$ (s; $\mathrm{CO}_{2}$ ), 128.71 (d, J = 6.04 Hz ; meta), 132.05 ( $\mathrm{d}, \mathrm{J}=$ 1.24 Hz ; para), 132.16 (d, J = 4.93 Hz ; ortho), 133.31 ( $\mathrm{d}, \mathrm{J}=51.61 \mathrm{~Hz}$; ipso)

Figure B7: Ir"'Cl( $\left.{ }^{13} \mathrm{CO}\right) \mathrm{O}_{2}\left[\mathrm{P}\left(\mathrm{C}_{6} \mathrm{H}_{5}\right)_{3}\right]_{2}$ (black trace). ${ }^{1} \mathrm{H}$ NMR ( 300 MHz , $\left[\mathrm{D}_{2}\right]$ Methylene Chloride, $30^{\circ} \mathrm{C}$ ): $\delta=7.44(\mathrm{~m} ; 2 \mathrm{H}), 7.53(\mathrm{~m}, 3 \mathrm{H})$.

Photolysis product - $\mathrm{OPPh}_{3}$ (blue trace). ${ }^{1} \mathrm{H}$ NMR $\left(300 \mathrm{MHz},\left[\mathrm{D}_{2}\right]\right.$ Methylene Chloride, $\left.30^{\circ} \mathrm{C}\right)$ : $\delta=7.48(\mathrm{~m} ; 2 \mathrm{H}), 7.55(\mathrm{~m}, 1 \mathrm{H}), 7.63(\mathrm{~m}, 2 \mathrm{H})$.

Figure B8: Low-temperature $500 \mathrm{MHz}{ }^{1} \mathrm{H}$ NMR of photoproducts following 12 hours irradiation of Vaska's $\mathrm{O}_{2}$ complex in $\mathrm{CD}_{2} \mathrm{Cl}_{2}$ under $7 \mathrm{PSI} \mathrm{O}_{2}$.

## Appendix C: DFT Calculated Energies and Geometries for "Chapter 4:

Intramolecular C-H Activation and Metallacycle Aromaticity in the Photochemistry of [FeFe]-Hydrogenase Model Compounds in LowTemperature Frozen Matrices"

4.1 B: $(\mu-\mathrm{pdt})\left[\mathrm{Fe}(\mathrm{CO})_{3}\right]_{2}$
